  EDatabaseError *E, TUpdateKind UpdateKind, TUpdateAction &UpdateAction)
{
  // Respond to errors here...
}
```

DataSet references the dataset to which updates are applied. You can use this dataset to access new and old values during error handling. The original values for fields in each record are stored in a read-only *TField* property called *OldValue*. Changed values are stored in the analogous *TField* property *NewValue*. These values provide the only way to inspect and change update

values in the event handler.

Warning: Do not call any dataset methods that change the current record (such as *Next* and *Prior*). Doing so causes the event handler to enter an endless loop.

The *E* parameter is usually of type *EDBEngineError*. From this exception type, you can extract an error message that you can display to users in your error handler. For example, the following code could be used to display the error message in the caption of a dialog box:

```
ErrorLabel.Caption := E.Message;
ErrorLabel->Caption = E->Message;
```

This parameter is also useful for determining the actual cause of the update error. You can extract specific error codes from *EDBEngineError*, and take appropriate action based on it.

The *UpdateKind* parameter describes the type of update that generated the error. Unless your error handler takes special actions based on the type of update being carried out, your code probably will not make use of this parameter.

The following table lists possible values for *UpdateKind*:

UpdateKind values

Value	Meaning
ukModify	Editing an existing record caused an error.
ukInsert	Inserting a new record caused an error.
ukDelete	Deleting an existing record caused an error.

UpdateAction tells the BDE how to proceed with the update process when your event handler exits. When your update error handler is first called, the value for this parameter is always set to *uaFail*. Based on the error condition for the record that caused the error and what you do to correct it, you typically set *UpdateAction* to a different value before exiting the handler:

- If your error handler can correct the error condition that caused the handler to be invoked, set *UpdateAction* to the appropriate action to take on exit. For error conditions you correct, set *UpdateAction* to *uaRetry* to apply the update for the record again.
- When set to *uaSkip*, the update for the row that caused the error is skipped, and the update for the record remains in the cache after all other updates are completed.
- Both *uaFail* and *uaAbort* cause the entire update operation to end. *uaFail* raises an exception and displays an error message. *uaAbort* raises a silent exception (does not display an error message).

The following code shows an *OnUpdateError* event handler that checks to see if the update error is related to a key violation, and if it is, it sets the *UpdateAction* parameter to *uaSkip*:

```
{ Add 'Bde' to your uses clause for this example }
if (E is EDBEngineError) then
  with EDBEngineError(E) do begin
    if Errors[ErrorCount - 1].ErrorCode = DBIERR_KEYVIOL then
      UpdateAction := uaSkip                    { key violation, just skip this record }
    else
      UpdateAction := uaAbort;              { don't know what's wrong, abort the update }
  end;
// include BDE.hpp in your unit file for this example
void __fastcall TForm1::DataSetUpdateError(TDataSet *DataSet,
  EDatabaseError *E, TUpdateKind UpdateKind, TUpdateAction &UpdateAction)
{
  UpdateAction = uaFail // initialize to fail the update
  if (E->ClassNameIs("EDBEngineError"))
  {
    EDBEngineError *pDBE = (EDBEngineError *)E;
    if (pDBE->Errors[pDBE->ErrorCount - 1]->ErrorCode == DBIERR_KEYVIOL)
      UpdateAction = uaSkip; // Key violation, just skip this record
  }
}
```

Note: If an error occurs during the application of cached updates, an exception is raised and an error message displayed. Unless the *ApplyUpdates* is called from within a try...except construct, an error message to the user displayed from inside your *OnUpdateError* event handler may cause your application to display the same error message twice. To prevent error message duplication, set *UpdateAction* to *uaAbort* to turn off the system-generated error message display.

3.2.3.7.10 Using transactions with the BDE

The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

Topics

Name	Description
Using Local Transactions (see page 1698)	The BDE supports local transactions against Paradox, dBASE, Access, and FoxPro tables. From a coding perspective, there is no difference to you between a local transaction and a transaction against a remote database server. **Note:** When using transactions with local Paradox, dBASE, Access, and FoxPro tables, set *TransIsolation* to *tiDirtyRead* instead of using the default value of *tiReadCommitted*. A BDE error is returned if *TransIsolation* is set to anything but *tiDirtyRead* for local tables. When a transaction is started against a local table, updates performed against the table are logged. Each log record contains the old record buffer for... more (see page 1698)
Using Passthrough SQL (see page 1699)	With passthrough SQL, you use a *TQuery*, *TStoredProc*, or *TUpdateSQL* component to send an SQL transaction control statement directly to a remote database server. The BDE does not process the SQL statement. Using passthrough SQL enables you to take direct advantage of the transaction controls offered by your server, especially when those controls are non-standard. To use passthrough SQL to control a transaction, you must • Install the proper SQL Links drivers. If you chose the "Typical" installation when installing Delphi, all SQL Links drivers are already properly installed. • Configure your network protocol. See your network administrator for more... more (see page 1699)
Using Transactions with the BDE (see page 1699)	By default, the BDE provides implicit transaction control for your applications. When an application is under implicit transaction control, a separate transaction is used for each record in a dataset that is written to the underlying database. Implicit transactions guarantee both a minimum of record update conflicts and a consistent view of the database. On the other hand, because each row of data written to a database takes place in its own transaction, implicit transaction control can lead to excessive network traffic and slower application performance. Also, implicit transaction control will not protect logical operations that span more than one... more (see page 1699)

3.2.3.7.10.1 Using Local Transactions

The BDE supports local transactions against Paradox, dBASE, Access, and FoxPro tables. From a coding perspective, there is no difference to you between a local transaction and a transaction against a remote database server.

Note: When using transactions with local Paradox, dBASE, Access, and FoxPro tables, set *TransIsolation* to *tiDirtyRead* instead of using the default value of *tiReadCommitted*. A BDE error is returned if *TransIsolation* is set to anything but *tiDirtyRead* for local tables.

When a transaction is started against a local table, updates performed against the table are logged. Each log record contains the old record buffer for a record. When a transaction is active, records that are updated are locked until the transaction is

committed or rolled back. On rollback, old record buffers are applied against updated records to restore them to their pre-update states.

Local transactions are more limited than transactions against SQL servers or ODBC drivers. In particular, the following limitations apply to local transactions:

- Automatic crash recovery is not provided.
- Data definition statements are not supported.
- Transactions cannot be run against temporary tables.
- *TransIsolation* level must only be set to *tiDirtyRead*.
- For Paradox, local transactions can only be performed on tables with valid indexes. Data cannot be rolled back on Paradox tables that do not have indexes.
- Only a limited number of records can be locked and modified. With Paradox tables, you are limited to 255 records. With dBASE the limit is 100.
- Transactions cannot be run against the BDE ASCII driver.
- Closing a cursor on a table during a transaction rolls back the transaction unless:
- Several tables are open.
- The cursor is closed on a table to which no changes were made.

Using Passthrough SQL (see page 1699)

3.2.3.7.10.2 Using Passthrough SQL

With passthrough SQL, you use a *TQuery*, *TStoredProc*, or *TUpdateSQL* component to send an SQL transaction control statement directly to a remote database server. The BDE does not process the SQL statement. Using passthrough SQL enables you to take direct advantage of the transaction controls offered by your server, especially when those controls are non-standard.

To use passthrough SQL to control a transaction, you must

- Install the proper SQL Links drivers. If you chose the "Typical" installation when installing Delphi, all SQL Links drivers are already properly installed.
- Configure your network protocol. See your network administrator for more information.
- Have access to a database on a remote server.
- Set SQLPASSTHRU MODE to NOT SHARED using the SQL Explorer. SQLPASSTHRU MODE specifies whether the BDE and passthrough SQL statements can share the same database connections. In most cases, SQLPASSTHRU MODE is set to SHARED AUTOCOMMIT. However, you can't share database connections when using transaction control statements.

  Note: When SQLPASSTHRU MODE is NOT SHARED, you must use separate database components for datasets that pass SQL transaction statements to the server and datasets that do not.

Using Local Transactions (see page 1698)

3.2.3.7.10.3 Using Transactions with the BDE

By default, the BDE provides implicit transaction control for your applications. When an application is under implicit transaction control, a separate transaction is used for each record in a dataset that is written to the underlying database. Implicit transactions guarantee both a minimum of record update conflicts and a consistent view of the database. On the other hand, because each row of data written to a database takes place in its own transaction, implicit transaction control can lead to excessive network traffic and slower application performance. Also, implicit transaction control will not protect logical operations that span more than one record.

If you explicitly control transactions, you can choose the most effective times to start, commit, and roll back your transactions. When you develop applications in a multi-user environment, particularly when your applications run against a remote SQL server, you should control transactions explicitly.

There are two mutually exclusive ways to control transactions explicitly in a BDE-based database application:

- Use the database component to control transactions. The main advantage to using the methods and properties of a database component is that it provides a clean, portable application that is not dependent on a particular database or server. This type of transaction control is supported by all database connection components, and described in Managing transactions (see page 1498).
- Use passthrough SQL (see page 1699) in a query component to pass SQL statements directly to remote SQL or ODBC servers. The main advantage to passthrough SQL is that you can use the advanced transaction management capabilities of a particular database server, such as schema caching. To understand the advantages of your server's transaction management model, see your database server documentation.

When working with local databases, you can only use the database component to create explicit transactions (local databases do not support passthrough SQL). However, there are limitations to using local transactions. For more information on using local transactions, see Using Local Transactions (see page 1698).

Note: You can minimize the number of transactions you need by caching updates. For more information about cached updates, see Using a Client Dataset to Cache Updates (see page 1731).

3.2.3.8 Using client datasets

Topics

Name	Description
Adding a New Index (see page 1709)	There are three ways to add indexes to a client dataset:
Adding Application-specific Information to the Data (see page 1709)	Application developers can add custom information to the client dataset's *Data* property. Because this information is bundled with the data packet, it is included when you save the data to a file or stream (see page 1740). It is copied when you copy the data to another dataset (see page 1714). Optionally, it can be included with the *Delta* property so that a provider can read this information when it receives updates from the client dataset. To save application-specific information with the *Data* property, use the SetOptionalParam method. This method lets you store an OleVariant that contains the data under a specific name. To... more (see page 1709)
Aggregating over groups of records (see page 1710)	By default, maintained aggregates are calculated so that they summarize all the records in the client dataset. However, you can specify that you want to summarize over the records in a group instead. This lets you provide intermediate summaries such as subtotals for groups of records that share a common field value. Before you can specify a maintained aggregate over a group of records, you must use an index that supports the appropriate grouping (see page 1734). Once you have an index that groups the data in the way you want it summarized, specify the *IndexName* and *GroupingLevel* properties of the aggregate... more (see page 1710)

Applying Updates (see page 1711)	Changes made to the client dataset's local copy of data are not sent to the database server (or XML document) until the client application calls the ApplyUpdates method. *ApplyUpdates* takes the changes in the change log, and sends them as a data packet (called Delta) to the provider. (Note that, when using most client datasets, the provider is internal to the client dataset.) *ApplyUpdates* takes a single parameter, *MaxErrors*, which indicates the maximum number of errors that the provider should tolerate before aborting the update process. If *MaxErrors* is *0*, then as soon as an update error occurs,... more (see page 1711)
Choosing the Type of Dataset for Caching Updates (see page 1711)	Delphi includes some specialized client dataset components for caching updates. Each client dataset is associated with a particular data access mechanism (see page 1572). These are listed in the following table: ***Specialized client datasets for caching updates***
Communicating with Providers Using Custom Events (see page 1712)	Client datasets communicate with a provider component through a special interface called IAppServer. If the provider is local, *IAppServer* is the interface to an automatically-generated object that handles all communication between the client dataset and its provider. If the provider is remote, *IAppServer* is the interface to a remote data module on the application server, or (in the case of a SOAP server) an interface generated by the connection component. *TClientDataSet* provides many opportunities for customizing the communication that uses the *IAppServer* interface. Before and after every *IAppServer* method call that is directed at the client dataset's provider, *TClientDataSet* receives... more (see page 1712)
Constraining Data Values (see page 1713)	Client datasets can enforce constraints on the edits a user makes to data. These constraints are applied when the user tries to post changes to the change log. You can always supply custom constraints. These let you provide your own, application-defined limits on what values users post to a client dataset. In addition, when client datasets represent server data that is accessed using the BDE, they also enforce data constraints imported from the database server. If the client dataset works with an external provider (see page 1732) component, the provider can control whether those constraints are sent to the client dataset, and the... more (see page 1713)
Copying Data from Another Dataset (see page 1714)	To copy the data from another dataset at design time, right click the client dataset and choose Assign Local Data. A dialog appears listing all the datasets available in your project. Select the one whose data and structure you want to copy and choose OK. When you copy the source dataset, your client dataset is automatically activated. To copy from another dataset at runtime, you can assign its data directly (see page 1738) or, if the source is another client dataset, you can clone the cursor (see page 1736).
Creating a New Dataset (see page 1714)	There are three ways to define and create client datasets that do not represent server data: • You can define and create a new client dataset using persistent fields or field and index definitions. This follows the same scheme as creating any table type dataset. See Creating and deleting tables (see page 1587) for details. • You can copy an existing dataset (see page 1714) (at design or runtime). • You can create a client dataset from an arbitrary XML document. See Converting XML documents into data packets (see page 1841) for details. Once the dataset is created, you can save it to a file. From then on, you do not need... more (see page 1714)
Deleting and Switching Indexes (see page 1715)	To remove an index you created for a client dataset, call DeleteIndex and specify the name of the index to remove. You cannot remove the DEFAULT_ORDER and CHANGEINDEX indexes. To use a different index when more than one index is available, use the IndexName property to select the index to use. At design time, you can select from available indexes in *IndexName* property drop-down box in the **Object Inspector**.

Editing Data (see page 1715)	Client datasets represent their data as an in-memory data packet. This packet is the value of the client dataset's Data property. By default, however, edits are not stored in the *Data* property. Instead the insertions, deletions, and modifications (made by users or programmatically) are stored in an internal change log, represented by the Delta property. Using a change log serves two purposes: • The change log is required for applying updates to a database server or external provider component. • The change log provides sophisticated support for undoing changes. The LogChanges property lets you disable logging. When *LogChanges* is *True*, changes... more (see page 1715)
Getting Parameters from the Application Server (see page 1715)	There are two circumstances when the client dataset needs to fetch parameter values: • The application needs the value of output parameters on a stored procedure. • The application wants to initialize the input parameters of a query or stored procedure to the current values on the source dataset. Client datasets store parameter values in their Params property. These values are refreshed with any output parameters when the client dataset fetches data from the source dataset (see page 1725). However, there may be times a *TClientDataSet* component in a client application needs output parameters when it is not fetching data. To fetch output parameters... more (see page 1715)
Handling Constraints from the Server (see page 1716)	When a database server defines constraints on what data is valid, it is useful if the client dataset knows about them. That way, the client dataset can ensure that user edits never violate those server constraints. As a result, such violations are never passed to the database server where they would be rejected. This means fewer updates generate error conditions during the updating process. Regardless of the source of data, you can duplicate such server constraints by explicitly adding them to the client dataset. This process is described in Constraining data values (see page 1713). It is more convenient, however, if the... more (see page 1716)
Indicating What Records Are Modified (see page 1717)	While the user edits a client dataset, you may find it useful to provide feedback about the edits that have been made. This is especially useful if you want to allow the user to undo specific edits, for example, by navigating to them and clicking an "Undo" button. The *UpdateStatus* method and *StatusFilter* properties are useful when providing feedback on what updates have occurred: UpdateStatus indicates what type of update, if any, has occurred for the current record. It can be any of the following values: • *usUnmodified* indicates that the current record is unchanged. • *usModified* indicates that the current record... more (see page 1717)
Intervening as Updates Are Applied (see page 1718)	When a client dataset applies its updates, the provider determines how to handle writing the insertions, deletions, and modifications to the database server or source dataset. When you use *TClientDataSet* with an external provider component, you can use the properties and events of that provider to influence the way updates are applied. These are described in Responding to client update requests (see page 1808). When the provider is internal, however, as it is for any client dataset associated with a data access mechanism, you can't set its properties or provide event handlers. As a result, the client dataset publishes one property and... more (see page 1718)

Limiting Records with Parameters (see page 1720)	If the client dataset is • a *TClientDataSet* instance whose associated provider represents a *TTable* or *TSQLTable* component • a *TSimpleDataSet or a TBDEClientDataSet* instance whose *CommandType* property is *ctTable* then it can use the Params property to limit the records that it caches in memory. Each parameter represents a field value that must be matched before a record can be included in the client dataset's data. This works much like a filter, except that with a filter, the records are still cached in memory, but unavailable. Each parameter name must match the name of a field. When using *TClientDataSet*, these... more (see page 1720)
Merging Changes into Data (see page 1720)	When you edit the data in a client dataset, all edits to the data exist only in an in-memory change log. This log can be maintained separately from the data itself, although it is completely transparent to objects that use the client dataset. That is, controls that navigate the client dataset or display its data see a view of the data that includes the changes. If you do not want to back out of changes, however, you should merge the change log into the data of the client dataset by calling the MergeChangeLog method. *MergeChangeLog* overwrites records in *Data* with... more (see page 1720)
Navigating Data in Client Datasets (see page 1721)	If an application uses standard data-aware controls, then a user can navigate through a client dataset's records using the built-in behavior of those controls. You can also navigate programmatically through records using standard dataset methods such as *First*, *Last*, *Next*, and *Prior*. For more information about these methods, see Navigating datasets (see page 1634). Unlike most datasets, client datasets can also position the cursor at a specific record in the dataset by using the RecNo property. Ordinarily an application uses *RecNo* to determine the record number of the current record. Client datasets can, however, set *RecNo* to a... more (see page 1721)
Obtaining Aggregate Values (see page 1721)	To get the value of a maintained aggregate, call the Value method of the *TAggregate* object that represents the aggregate. *Value* returns the maintained aggregate for the group that contains the current record of the client dataset. When you are summarizing over the entire client dataset, you can call *Value* at any time to obtain the maintained aggregate. However, when you are summarizing over grouped information, you must be careful to ensure that the current record is in the group whose summary you want. Because of this, it is a good idea to obtain aggregate values at clearly specified times,... more (see page 1721)
Overriding the Dataset On the Application Server (see page 1722)	The client datasets that are associated with a particular data access mechanism use the CommandText and *Com*mandType properties to specify the data they represent. When using *TClientDataSet*, however, the data is specified by the source dataset, not the client dataset. Typically, this source dataset has a property that specifies an SQL statement to generate the data or the name of a database table or stored procedure. If the provider allows, *TClientDataSet* can override the property on the source dataset that indicates what data it represents. That is, if the provider permits, the client dataset's CommandText property replaces the... more (see page 1722)

Overview of Using Cached Updates (see page 1723)	To use cached updates, the following order of processes must occur in an application: **Indicate the data you want to edit.** How you do this depends on the type of client dataset you are using: • If you are using *TClientDataSet*, Specify the provider component (see page 1729) that represent the data you want to edit. • If you are using a client dataset associated with a particular data access mechanism, you must • Identify the database server by setting the *DBConnection* property to an appropriate connection component. • Indicate what data you want to see by specifying the CommandText and *CommandType* properties. *CommandType* indicates whether... more (see page 1723)
Passing Parameters to the Source Dataset (see page 1723)	Client datasets can pass parameters to the source dataset to specify what data they want provided in the data packets it sends. These parameters can specify • Input parameter values for a query or stored procedure that is run on the application server (see page 1727) • Field values that limit the records sent in data packets (see page 1720) You can specify parameter values that your client dataset sends to the source dataset at design time or at runtime. At design time, select the client dataset and double-click the Params property in the **Object Inspector**. This brings up the collection editor, where you can add, delete,... more (see page 1723)
Refreshing Records (see page 1724)	Client datasets work with an in-memory snapshot of the data from the source dataset. If the source dataset represents server data, then as time elapses other users may modify that data. The data in the client dataset becomes a less accurate picture of the underlying data. Like any other dataset, client datasets have a Refresh method that updates its records to match the current values on the server. However, calling *Refresh* only works if there are no edits in the change log. Calling *Refresh* when there are unapplied edits results in an exception. Client datasets can also update the data... more (see page 1724)
Representing Calculated Values (see page 1725)	As with any dataset, you can add calculated fields (see page 1872) to your client dataset. These are fields whose values you calculate dynamically, usually based on the values of other fields in the same record. Client datasets, however, let you optimize when fields are calculated by using internally calculated fields (see page 1735). You can also tell client datasets to create calculated values that summarize the data in several records using maintained aggregates (see page 1735).
Requesting Data from the Source Dataset or Document (see page 1725)	Client datasets can control how they fetch their data packets from a provider. By default, they retrieve all records from the source dataset. This is true whether the source dataset and provider are internal components (as with *TBDEClientDataSet,TSimpleDataSet,* and *TIBClientDataSet*), or separate components that supply the data for *TClientDataSet*. You can change how the client dataset fetches records using the *PacketRecords* and *FetchOnDemand* properties.
Saving Changes (see page 1726)	Client datasets use different mechanisms for incorporating changes from the change log, depending on whether the client datasets stores its data in a file or represents data obtained through a provider. Whichever mechanism is used, the change log is automatically emptied when all updates have been incorporated. File-based applications can simply merge the changes into the local cache represented by the *Data* property. They do not need to worry about resolving local edits with changes made by other users. To merge the change log into the *Data* property, call the *MergeChangeLog* method. Merging changes into data (see page 1720) describes this process. You... more (see page 1726)

Sending Query or Stored Procedure Parameters (see page 1727)	When the client dataset's *CommandType* property is *ctQuery* or *ctStoredProc*, or, if the client dataset is a *TClientDataSet* instance, when the associated provider represents the results of a query or stored procedure, you can use the Params property to specify parameter values. When the client dataset requests data from the source dataset (see page 1725) or uses its Execute method to run a query or stored procedure that does not return a dataset, it passes these parameter values along with the request for data or the execute command. When the provider receives these parameter values, it assigns them to its associated dataset.... more (see page 1727)
Setting Up a Simple Dataset (see page 1727)	Setting up a simple dataset requires two essential steps. Set up: 1. The connection information. 2. The dataset information. The following steps describe setting up a simple dataset in more detail.
Sorting and Indexing (see page 1728)	Using indexes provides several benefits to your applications: • They allow client datasets to locate data quickly. • They let you apply ranges to limit the available records. • They let your application set up relationships with other datasets such as lookup tables or master/detail forms. • They specify the order in which records appear. If a client dataset represents server data or uses an external provider, it inherits a default index and sort order based on the data it receives. The default index is called DEFAULT_ORDER. You can use this ordering, but you cannot change or delete the index. In addition to the... more (see page 1728)
Specifying a Provider (see page 1729)	Unlike the client datasets that are associated with a data access mechanism, *TClientDataSet* has no internal provider component to package data or apply updates. If you want it to represent data from a source dataset or XML document, therefore, you must associated the client dataset with an external provider component. The way you associate *TClientDataSet* with a provider depends on whether the provider is in the same application as the client dataset or on a remote application server running on another system.
Specifying Aggregates (see page 1730)	To specify that you want to calculate summaries over the records in a client dataset, use the Aggregates property. *Aggregates* is a collection of aggregate specifications (TAggregate). You can add aggregate specifications to your client dataset using the Collection Editor at design time, or using the Add method of *Aggregates* at runtime. If you want to create field components for the aggregates, create persistent fields for the aggregated values in the Fields Editor. **Note:** When you create aggregated fields, the appropriate aggregate objects are added to the client dataset's *Aggregates* property automatically. Do not add them explicitly when creating aggregated (see page 1856)... more (see page 1730)
Undoing Changes (see page 1730)	Even though a record's original version remains unchanged in *Data*, each time a user edits a record, leaves it, and returns to it, the user sees the last changed version of the record. If a user or application edits a record a number of times, each changed version of the record is stored in the change log as a separate entry. Storing each change to a record makes it possible to support multiple levels of undo operations should it be necessary to restore a record's previous state: • To remove the last change to a record, call UndoLastChange. *UndoLastChange* takes... more (see page 1730)

Updating Records (see page 1731)	The contents of the change log are stored as a data packet in the client dataset's *Delta* property. To make the changes in *Delta* permanent, the client dataset must apply them to the database (or source dataset or XML document). When a client applies updates to the server, the following steps occur: 1. The client application calls the ApplyUpdates method (see page 1711) of a client dataset object. This method passes the contents of the client dataset's *Delta* property to the (internal or external) provider. *Delta* is a data packet that contains a client dataset's updated, inserted, and deleted records. 2. The provider applies the... more (see page 1731)
Using a Client Dataset to Cache Updates (see page 1731)	By default, when you edit data in most datasets, every time you delete or post a record, the dataset generates a transaction, deletes or writes that record to the database server, and commits the transaction. If there is a problem writing changes to the database, your application is notified immediately: the dataset raises an exception when you post the record. If your dataset uses a remote database server, this approach can degrade performance due to network traffic between your application and the server every time you move to a new record after editing the current record. To minimize the network... more (see page 1731)
Using a Client Dataset with a Provider (see page 1732)	A client dataset uses a provider to supply it with data and apply updates when • It caches updates from a database server or another dataset. • It represents the data in an XML document. • It stores the data in the client portion of a multi-tiered application. For any client dataset other than *TClientDataSet*, this provider is internal, and so not directly accessible by the application. With *TClientDataSet*, the provider is an external component that links the client dataset to an external source of data. An external provider component can reside in the same application as the client dataset, or... more (see page 1732)
Using a Client Dataset with File-based Data (see page 1733)	Client datasets can work with dedicated files on disk as well as server data. This allows them to be used in file-based database applications (see page 1564) and "briefcase model" applications (see page 1565). The special files that client datasets use for their data are called MyBase. **Tip:** All client datasets are appropriate for a briefcase model application, but for a pure MyBase application (one that does not use a provider), it is preferable to use *TClientDataSet*, because it involves less overhead. In a pure MyBase application, the client application cannot get table definitions and data from the server, and there is no server... more (see page 1733)
Using a Simple Dataset (see page 1733)	*TSimpleDataSet* is a special type of client dataset designed for simple two-tiered applications. Like a unidirectional dataset, it can use an SQL connection component to connect to a database server and specify an SQL statement to execute on that server. Like other client datasets, it buffers data in memory to allow full navigation and editing support. *TSimpleDataSet* works the same way as a generic client dataset (*TClientDataSet*) that is linked to a unidirectional dataset by a dataset provider. In fact, *TSimpleDataSet* has its own, internal provider, which it uses to communicate with an internally created unidirectional dataset. Using... more (see page 1733)
Using Indexes to Group Data (see page 1734)	When you use an index in your client dataset, it automatically imposes a sort order on the records. Because of this order, adjacent records usually contain duplicate values on the fields that make up the index. For example, consider the following fragment from an orders table that is indexed on the SalesRep and Customer fields:

Using Internally Calculated Fields in Client Datasets (see page 1735)	In other datasets, your application must compute the value of calculated fields every time the record changes or the user edits any fields in the current record. It does this in an OnCalcFields event handler. While you can still do this, client datasets let you minimize the number of times calculated fields must be recomputed by saving calculated values in the client dataset's data. When calculated values are saved with the client dataset, they must still be recomputed when the user edits the current record, but your application need not recompute values every time the current record changes. To save... more (see page 1735)
Using Maintained Aggregates (see page 1735)	Client datasets provide support for summarizing data over groups of records. Because these summaries are automatically updated as you edit the data in the dataset, this summarized data is called a "maintained aggregate." In their simplest form, maintained aggregates let you obtain information such as the sum of all values in a column of the client dataset. They are flexible enough, however, to support a variety of summary calculations and to provide subtotals over groups of records defined by a field in an index that supports grouping (see page 1734). The following topics describe how to • Specify aggregates (see page 1730). • Aggregate Over Groups (see page 1710)... more (see page 1735)
When to Use TSimpleDataSet (see page 1736)	*TSimpleDataSet* is intended for use in a simple two-tiered database applications and briefcase model applications. It provides an easy-to-set up component for linking to the database server, fetching data, caching updates, and applying them back to the server. It can be used in most two-tiered applications. There are times, however, when it is more appropriate to use *TClientDataSet*: • If you are not using data from a database server (for example, if you are using a dedicated file on disk (see page 1564)), then *TClientDataSet* has the advantage of less overhead. • Only *TClientDataSet* can be used in a multi-tiered database application .... more (see page 1736)
Cloning a Client Dataset Cursor (see page 1736)	Client datasets use the *CloneCursor* method to let you work with a second view of the data at runtime. *CloneCursor* lets a second client dataset share the original client dataset's data. This is less expensive than copying all the original data, but, because the data is shared, the second client dataset can't modify the data without affecting the original client dataset. *CloneCursor* takes three parameters: *Source* specifies the client dataset to clone. The last two parameters (*Reset* and *KeepSettings*) indicate whether to copy information other than the data. This information includes any filters, the current index, links to... more (see page 1736)
Working with Data Using a Client Dataset (see page 1737)	Like any dataset, you can use client datasets to supply the data for data-aware controls using a data source component. See Using data controls (see page 1778) for information on how to display database information in data-aware controls. Client datasets implement all the properties an methods inherited from *TDataSet*. For a complete introduction to this generic dataset behavior, see Understanding datasets (see page 1632). In addition, client datasets implement many of the features common to table type datasets (see page 1620) such as • Sorting records with indexes (see page 1609). • Using Indexes to search for records (see page 1615). • Limiting records with ranges (see page 1597). • Creating master/detail relationships (see page 1590). • Controlling read/write access (see page 1587)... more (see page 1737)

Reconciling Update Errors (see page 1737)	There are two events that let you handle errors that occur during the update process: • During the update process, the internal provider generates an OnUpdateError event every time it encounters an update that it can't handle. If you correct the problem in an *OnUpdateError* event handler, then the error does not count toward the maximum number of errors passed to the *ApplyUpdates* method. This event only occurs for client datasets that use an internal provider. If you are using *TClientDataSet*, you can use the provider component's *OnUpdateError* event instead. • After the entire update operation is finished, the client dataset... more (see page 1737)
Assigning Data Directly (see page 1738)	You can use the client dataset's *Data* property to assign data to a client dataset from another dataset. *Data* is a data packet in the form of an OleVariant. A data packet can come from another client dataset or from any other dataset by using a provider. Once a data packet is assigned to *Data*, its contents are displayed automatically in data-aware controls connected to the client dataset by a data source component. When you open a client dataset that represents server data or that uses an external provider component, data packets are automatically assigned to *Data*. When... more (see page 1738)
Loading Data from a File or Stream (see page 1739)	To load data from a file, call a client dataset's LoadFromFile method. *LoadFromFile* takes one parameter, a string that specifies the file from which to read data. The file name can be a fully qualified path name, if appropriate. If you always load the client dataset's data from the same file, you can use the FileName property instead. If *FileName* names an existing file, the data is automatically loaded when the client dataset is opened. To load data from a stream, call the client dataset's *LoadFromStream* method. *LoadFromStream* takes one parameter, a stream object that supplies the data. The data... more (see page 1739)
Saving Data to a File or Stream (see page 1740)	Even when you have merged changes into the data of a client dataset, this data still exists only in memory. While it persists if you close the client dataset and reopen it in your application, it will disappear when your application shuts down. To make the data permanent, it must be written to disk. Write changes to disk using the SaveToFile method. *SaveToFile* takes one parameter, a string that specifies the file into which to write data. The file name can be a fully qualified path name, if appropriate. If the file already exists, its current contents are completely overwritten.... more (see page 1740)
Using Client Datasets: Overview (see page 1740)	Client datasets are specialized datasets that hold all their data in memory. The support for manipulating the data they store in memory is provided by midaslib.dcu or midas.dll. The format client datasets use for storing data is self-contained and easily transported, which allows client datasets to • Read from and write to dedicated files on disk, acting as a file-based dataset. Properties and methods supporting this mechanism are described in Using a client dataset with file-based data (see page 1733). • Cache updates for data from a database server. Client dataset features that support cached updates are described in Using a client dataset to (see page 1731)... more (see page 1740)
Limiting What Records Appear (see page 1741)	To restrict users to a subset of available data on a temporary basis, applications can use ranges and filters. When you apply a range or a filter, the client dataset does not display all the data in its in-memory cache. Instead, it only displays the data that meets the range or filter conditions. For more information about using filters, see Displaying and editing a subset of data using filters (see page 1631). For more information about ranges, see Limiting records with ranges (see page 1597). With most datasets, filter strings are parsed into SQL commands that are then implemented on the database server. Because... more (see page 1741)

3.2.3.8.1 Adding a New Index

There are three ways to add indexes to a client dataset:

Methods	Description
Use the IndexFieldNames property	To create a temporary index at runtime that sorts the records in the client dataset, you can use the IndexFieldNames property. Specify field names, separated by semicolons. Ordering of field names in the list determines their order in the index. This is the least powerful method of adding indexes. You can't specify a descending or case-insensitive index, and the resulting indexes do not support grouping (see page 1734). These indexes do not persist when you close the dataset, and are not saved when you save the client dataset to a file.
Call AddIndex	To create an index at runtime that can be used for grouping, call AddIndex. *AddIndex* lets you specify the properties of the index, including: The name of the index. This can be used for switching indexes (see page 1715) at runtime. The fields that make up the index. The index uses these fields to sort records and to locate records that have specific values on these fields. How the index sorts records. By default, indexes impose an ascending sort order (based on the machine's locale). This default sort order is case-sensitive. You can set options to make the entire index case-insensitive or to sort in descending order. Alternately, you can provide a list of fields to be sorted case-insensitively and a list of fields to be sorted in descending order. The default level of grouping support (see page 1734) for the index. Indexes created with *AddIndex* do not persist when the client dataset is closed. (That is, they are lost when you reopen the client dataset). You can"t call *AddIndex* when the dataset is closed. Indexes you add using *AddIndex* are not saved when you save the client dataset to a file.
Use the IndexDefs property	The third way to create an index is at the time the client dataset is created. Before creating the client dataset, specify the desired indexes using the *IndexDefs* property. The indexes are then created along with the underlying dataset when you call CreateDataSet. See Creating and deleting tables (see page 1587) for more information about creating client datasets. As with *AddIndex*, indexes you create with the dataset support grouping, can sort in ascending order on some fields and descending order on others, and can be case insensitive on some fields and case sensitive on others.

Tip: You can index and sort on internally calculated fields with client datasets.

Deleting and Switching Indexes (see page 1715)

Using Indexes to Group Data (see page 1734)

3.2.3.8.2 Adding Application-specific Information to the Data

Application developers can add custom information to the client dataset's *Data* property. Because this information is bundled with the data packet, it is included when you save the data to a file or stream (see page 1740). It is copied when you copy the data to another dataset (see page 1714). Optionally, it can be included with the *Delta* property so that a provider can read this information when it receives updates from the client dataset.

To save application-specific information with the *Data* property, use the SetOptionalParam method. This method lets you store an OleVariant that contains the data under a specific name.

To retrieve this application-specific information, use the GetOptionalParam method, passing in the name that was used when the information was stored.

Adding Custom Information to Data Packets (see page 1808)

Copying Data from Another Dataset (see page 1714)

3.2.3.8.3 Aggregating over groups of records

By default, maintained aggregates are calculated so that they summarize all the records in the client dataset. However, you can specify that you want to summarize over the records in a group instead. This lets you provide intermediate summaries such as subtotals for groups of records that share a common field value. Before you can specify a maintained aggregate over a group of records, you must use an index that supports the appropriate grouping (see page 1734).

Once you have an index that groups the data in the way you want it summarized, specify the *IndexName* and *GroupingLevel* properties of the aggregate to indicate what index it uses, and which group or subgroup on that index defines the records it summarizes.

For example, consider the following fragment from an orders table that is grouped by SalesRep and, within SalesRep, by Customer:

SalesRep	Customer	OrderNo	Amount
1	1	5	100
1	1	2	50
1	2	3	200
1	2	6	75
2	1	1	10
2	3	4	200

The following code sets up a maintained aggregate that indicates the total amount for each sales representative:

```
Agg.Expression := 'Sum(Amount)';
Agg.IndexName := 'SalesCust';
Agg.GroupingLevel := 1;
Agg.AggregateName := 'Total for Rep';
Agg->Expression = "Sum(Amount)";
Agg->IndexName = "SalesCust";
Agg->GroupingLevel = 1;
Agg->AggregateName = "Total for Rep";
```

To add an aggregate that summarizes for each customer within a given sales representative, create a maintained aggregate with level 2.

Maintained aggregates that summarize over a group of records are associated with a specific index. The *Aggregates* property can include aggregates that use different indexes. However, only the aggregates that summarize over the entire dataset and those that use the current index are valid. Changing the current index changes which aggregates are valid. To determine which

aggregates are valid at any time, use the *ActiveAggs* property.

Specifying Aggregates (see page 1730)

Obtaining Aggregate Values (see page 1721)

3.2.3.8.4 Applying Updates

Changes made to the client dataset's local copy of data are not sent to the database server (or XML document) until the client application calls the ApplyUpdates method. *ApplyUpdates* takes the changes in the change log, and sends them as a data packet (called Delta) to the provider. (Note that, when using most client datasets, the provider is internal to the client dataset.)

ApplyUpdates takes a single parameter, *MaxErrors*, which indicates the maximum number of errors that the provider should tolerate before aborting the update process. If *MaxErrors* is *0*, then as soon as an update error occurs, the entire update process is terminated. No changes are written to the database, and the client dataset's change log remains intact. If *MaxErrors* is *-1*, any number of errors is tolerated, and the change log contains all records that could not be successfully applied. If *MaxErrors* is a positive value, and more errors occur than are permitted by *MaxErrors*, all updates are aborted. If fewer errors occur than specified by *MaxErrors*, all records successfully applied are automatically cleared from the client dataset's change log.

ApplyUpdates returns the number of actual errors encountered, which is always less than or equal to *MaxErrors* plus one. This return value indicates the number of records that could not be written to the database.

The client dataset's *ApplyUpdates* method does the following:

- It indirectly calls the provider's ApplyUpdates method. The provider's *ApplyUpdates* method writes the updates to the database, source dataset, or XML document and attempts to correct any errors it encounters. Records that it cannot apply because of error conditions are sent back to the client dataset.
- The client dataset 's *ApplyUpdates* method then attempts to reconcile these problem records by calling the Reconcile method. *Reconcile* is an error-handling routine that calls the OnReconcileError event handler. You must code the *OnReconcileError* event handler to correct errors. For details about using *OnReconcileError*, see Reconciling Update Errors (see page 1737).
- Finally, *Reconcile* removes successfully applied changes from the change log and updates Data to reflect the newly updated records. When *Reconcile* completes, *ApplyUpdates* reports the number of errors that occurred.

  Warning: In some cases, the provider can't determine how to apply updates (for example, when applying updates from a stored procedure or multi-table join). Client datasets and provider components generate events that let you handle these situations. See Intervening as updates are applied (see page 1718) for details.

  Tip: If the provider is on a stateless application server, you may want to communicate with it about persistent state information before or after you apply updates. *TClientDataSet* receives a BeforeApplyUpdates event before the updates are sent, which lets you send persistent state information to the server. After the updates are applied (but before the reconcile process), *TClientDataSet* receives an AfterApplyUpdates event where you can respond to any persistent state information returned by the application server.

Intervening as Updates Are Applied (see page 1718)

3.2.3.8.5 Choosing the Type of Dataset for Caching Updates

Delphi includes some specialized client dataset components for caching updates. Each client dataset is associated with a particular data access mechanism (see page 1572). These are listed in the following table:

Specialized client datasets for caching updates

Client dataset	Data access mechanism
TSimpleDataSet	dbExpress
TIBClientDataSet	InterBase Express

Generic client dataset for caching updates

Client dataset	Data access mechanism
TClientDataSet	dbExpress, Blackfish SQL, dbGo, BDE

You can cache updates using the generic client dataset (TClientDataSet) with an external provider and source dataset. For information about using *TClientDataSet* with an external provider, see Using a client dataset with a provider (see page 1732).

Note: The specialized client datasets associated with each data access mechanism actually use a provider and source dataset as well. However, both the provider and the source dataset are internal to the client dataset.

It is simplest to use one of the specialized client datasets to cache updates. However, there are times when it is preferable to use *TClientDataSet* with an external provider:

- If you are using a data access mechanism that does not have a specialized client dataset, you must use *TClientDataSet* with an external provider component. For example, if the data comes from an XML document or custom dataset.
- If you are working with tables that are related in a master/detail relationship, you should use *TClientDataSet* and connect it, using a provider, to the master table of two source datasets linked in a master/detail relationship. The client dataset sees the detail dataset as a nested dataset field. This approach is necessary so that updates to master and detail tables can be applied in the correct order.
- If you want to code event handlers that respond to the communication between the client dataset and the provider (for example, before and after the client dataset fetches records from the provider), you must use *TClientDataSet* with an external provider component. The specialized client datasets publish the most important events for applying updates (*OnReconcileError*, *BeforeUpdateRecord* and OnGetTableName), but do not publish the events surrounding communication between the client dataset and its provider, because they are intended primarily for multi-tiered applications.

Overview of Using Cached Updates (see page 1723)

Updating Records (see page 1731)

Indicating What Records Are Modified (see page 1717)

3.2.3.8.6 Communicating with Providers Using Custom Events

Client datasets communicate with a provider component through a special interface called IAppServer. If the provider is local, *IAppServer* is the interface to an automatically-generated object that handles all communication between the client dataset and its provider. If the provider is remote, *IAppServer* is the interface to a remote data module on the application server, or (in the case of a SOAP server) an interface generated by the connection component.

TClientDataSet provides many opportunities for customizing the communication that uses the *IAppServer* interface. Before and after every *IAppServer* method call that is directed at the client dataset's provider, *TClientDataSet* receives special events that allow it to communicate arbitrary information with its provider. These events are matched with similar events on the provider. Thus for example, when the client dataset calls its *ApplyUpdates* method, the following events occur:

1. The client dataset receives a *BeforeApplyUpdates* event, where it specifies arbitrary custom information in an OleVariant called *OwnerData*.
2. The provider receives a *BeforeApplyUpdates* event, where it can respond to the *OwnerData* from the client dataset and update the value of *OwnerData* to new information.

3. The provider goes through its normal process of assembling a data packet (including all the accompanying events).
4. The provider receives an *AfterApplyUpdates* event, where it can respond to the current value of *OwnerData* and update it to a value for the client dataset.
5. The client dataset receives an *AfterApplyUpdates* event, where it can respond to the returned value of *OwnerData*.

Every other *IAppServer* method call is accompanied by a similar set of *BeforeXXX* and *AfterXXX* events that let you customize the communication between client dataset and provider.

In addition, the client dataset has a special method, DataRequest, whose only purpose is to allow application-specific communication with the provider. When the client dataset calls *DataRequest*, it passes an OleVariant as a parameter that can contain any information you want. This, in turn, generates an is the OnDataRequest event on the provider, where you can respond in any application-defined way and return a value to the client dataset.

Refreshing Records (see page 1724)

Overriding the Dataset On the Application Server (see page 1722)

3.2.3.8.7 Constraining Data Values

Client datasets can enforce constraints on the edits a user makes to data. These constraints are applied when the user tries to post changes to the change log. You can always supply custom constraints. These let you provide your own, application-defined limits on what values users post to a client dataset.

In addition, when client datasets represent server data that is accessed using the BDE, they also enforce data constraints imported from the database server. If the client dataset works with an external provider (see page 1732) component, the provider can control whether those constraints are sent to the client dataset, and the client dataset can control whether it uses them. For details on how the provider controls whether constraints are included in data packets, see Handling server constraints (see page 1814). For details on how and why client dataset can turn off enforcement of server constraints, see Handling constraints from the server (see page 1716).

Specifying custom constraints

You can use the properties of the client dataset's field components to impose your own constraints on what data users can enter. Each field component has two properties that you can use to specify constraints:

- The DefaultExpression property defines a default value that is assigned to the field if the user does not enter a value. Note that if the database server or source dataset also assigns a default expression for the field, the client dataset's version takes precedence because it is assigned before the update is applied back to the database server or source dataset.
- The CustomConstraint property lets you assign a constraint condition that must be met before a field value can be posted. Custom constraints defined this way are applied in addition to any constraints imported from the server. For more information about working with custom constraints on field components, see Creating a custom constraint (see page 1855).

In addition, you can create record-level constraints using the client dataset's Constraints property. *Constraints* is a collection of TCheckConstraint objects, where each object represents a separate condition. Use the CustomConstraint property of a *TCheckConstraint* object to add your own constraints that are checked when you post records.

3.2.3.8.8 Copying Data from Another Dataset

To copy the data from another dataset at design time, right click the client dataset and choose Assign Local Data. A dialog appears listing all the datasets available in your project. Select the one whose data and structure you want to copy and choose OK. When you copy the source dataset, your client dataset is automatically activated.

To copy from another dataset at runtime, you can assign its data directly (see page 1738) or, if the source is another client dataset, you can clone the cursor (see page 1736).

Representing Calculated Values (see page 1725)

Adding Application-specific Information to the Data (see page 1709)

3.2.3.8.9 Creating a New Dataset

There are three ways to define and create client datasets that do not represent server data:

- You can define and create a new client dataset using persistent fields or field and index definitions. This follows the same scheme as creating any table type dataset. See Creating and deleting tables (see page 1587) for details.
- You can copy an existing dataset (see page 1714) (at design or runtime).
- You can create a client dataset from an arbitrary XML document. See Converting XML documents into data packets (see page 1841) for details.

Once the dataset is created, you can save it to a file. From then on, you do not need to recreate the table, only load it from the file you saved. When beginning a file-based database application, you may want to first create and save empty files for your datasets before writing the application itself. This way, you start with the metadata for your client dataset already defined, making it easier to set up the user interface.

Merging Changes into Data (see page 1720)

Saving Data to a File or Stream (see page 1740)

3.2.3.8.10 Deleting and Switching Indexes

To remove an index you created for a client dataset, call DeleteIndex and specify the name of the index to remove. You cannot remove the DEFAULT_ORDER and CHANGEINDEX indexes.

To use a different index when more than one index is available, use the IndexName property to select the index to use. At design time, you can select from available indexes in *IndexName* property drop-down box in the **Object Inspector**.

See Also

Adding a New Index (see page 1709)

Using Indexes to Group Data (see page 1734)

3.2.3.8.11 Editing Data

Client datasets represent their data as an in-memory data packet. This packet is the value of the client dataset's Data property. By default, however, edits are not stored in the *Data* property. Instead the insertions, deletions, and modifications (made by users or programmatically) are stored in an internal change log, represented by the Delta property. Using a change log serves two purposes:

- The change log is required for applying updates to a database server or external provider component.
- The change log provides sophisticated support for undoing changes.

The LogChanges property lets you disable logging. When *LogChanges* is *True*, changes are recorded in the log. When *LogChanges* is *False*, changes are made directly to the *Data* property. You can disable the change log in file-based applications if you do not want the undo support.

Edits in the change log remain there until they are removed by the application. Applications remove edits when

- Undoing changes (see page 1730)
- Saving changes (see page 1726)

  Note: Saving the client dataset to a file does not remove edits from the change log. When you reload the dataset, the *Data* and *Delta* properties are the same as they were when the data was saved.

Copying Data from Another Dataset (see page 1714)

3.2.3.8.12 Getting Parameters from the Application Server

There are two circumstances when the client dataset needs to fetch parameter values:

- The application needs the value of output parameters on a stored procedure.
- The application wants to initialize the input parameters of a query or stored procedure to the current values on the source dataset.

Client datasets store parameter values in their Params property. These values are refreshed with any output parameters when the client dataset fetches data from the source dataset (see page 1725). However, there may be times a *TClientDataSet* component in a client application needs output parameters when it is not fetching data.

To fetch output parameters when not fetching records, or to initialize input parameters, the client dataset can request parameter values from the source dataset by calling the FetchParams method. The parameters are returned in a data packet from the provider and assigned to the client dataset's *Params* property.

At design time, the *Params* property can be initialized by right-clicking the client dataset and choosing Fetch Params.

Note: There is never a need to call *FetchParams* when the client dataset uses an internal provider and source dataset, because the *Params* property always reflects the parameters of the internal source dataset. With *TClientDataSet*, the *FetchParams* method (or the Fetch Params command) only works if the client dataset is connected to a provider whose associated dataset can supply parameters. For example, if the source dataset is a table type dataset, there are no parameters to fetch.

The *Params* property can also be used to pass parameter values to the source dataset. For details on how to do this, see Passing parameters to the source dataset (see page 1723).

If the provider is on a separate system as part of a stateless application server, you can't use *FetchParams* to retrieve output parameters. In a stateless application server, other clients can change and rerun the query or stored procedure, changing output parameters before the call to *FetchParams*. To retrieve output parameters from a stateless application server, use the Execute method. If the provider is associated with a query or stored procedure, *Execute* tells the provider to execute the query or stored procedure and return any output parameters. These returned parameters are then used to automatically update the *Params* property.

3.2.3.8.13 Handling Constraints from the Server

When a database server defines constraints on what data is valid, it is useful if the client dataset knows about them. That way, the client dataset can ensure that user edits never violate those server constraints. As a result, such violations are never passed to the database server where they would be rejected. This means fewer updates generate error conditions during the updating process.

Regardless of the source of data, you can duplicate such server constraints by explicitly adding them to the client dataset. This process is described in Constraining data values (see page 1713).

It is more convenient, however, if the server constraints are automatically included in data packets. Then you need not explicitly specify default expressions and constraints, and the client dataset changes the values it enforces when the server constraints change. By default, this is exactly what happens: if the source dataset is aware of server constraints, the provider automatically includes them in data packets and the client dataset enforces them when the user posts edits to the change log.

Note: Only datasets that use the BDE can import constraints from the server. This means that server constraints are only included in data packets when using *TBDEClientDataSet* or *TClientDataSet* with a provider that represents a BDE-based dataset. For more information on how to import server constraints and how to prevent a provider from including them in data packets, see Handling server constraints (see page 1814).

Note: For more information on working with the constraints once they have been imported, see Using server constraints (see page 1863).

While importing server constraints and expressions is an extremely valuable feature that helps an application preserve data integrity, there may be times when it needs to disable constraints on a temporary basis. For example, if a server constraint is based on the current maximum value of a field, but the client dataset uses incremental fetching, the current maximum value for a field in the client dataset may differ from the maximum value on the database server, and constraints may be invoked differently. In another case, if a client dataset applies a filter to records when constraints are enabled, the filter may interfere in unintended ways with constraint conditions. In each of these cases, an application may disable constraint-checking.

To disable constraints temporarily, call the DisableConstraints method. Each time *DisableConstraints* is called, a reference count is incremented. While the reference count is greater than zero, constraints are not enforced on the client dataset.

To reenable constraints for the client dataset, call the dataset's EnableConstraints method. Each call to *EnableConstraints* decrements the reference count. When the reference count is zero, constraints are enabled again.

Tip: Always call *DisableConstraints* and *EnableConstraints* in paired blocks to ensure that constraints are enabled when you intend them to be.

3.2.3.8.14 Indicating What Records Are Modified

While the user edits a client dataset, you may find it useful to provide feedback about the edits that have been made. This is especially useful if you want to allow the user to undo specific edits, for example, by navigating to them and clicking an "Undo" button.

The *UpdateStatus* method and *StatusFilter* properties are useful when providing feedback on what updates have occurred:

UpdateStatus indicates what type of update, if any, has occurred for the current record. It can be any of the following values:

- *usUnmodified* indicates that the current record is unchanged.
- *usModified* indicates that the current record has been edited.
- *usInserted* indicates a record that was inserted by the user.
- *usDeleted* indicates a record that was deleted by the user.

StatusFilter controls what type of updates in the change log are visible. *StatusFilter* works on cached records in much the same way as filters work on regular data. *StatusFilter* is a set, so it can contain any combination of the following values:

- *usUnmodified* indicates an unmodified record.
- *usModified* indicates a modified record.
- *usInserted* indicates an inserted record.
- *usDeleted* indicates a deleted record.

By default, *StatusFilter* is the set [*usModified*, *usInserted*, *usUnmodified*]. You can add *usDeleted* to this set to provide feedback

about deleted records as well.

Note: *UpdateStatus* and *StatusFilter* are also useful in *BeforeUpdateRecord* and *OnReconcileError* event handlers. For information about *BeforeUpdateRecord*, see Intervening as updates are applied (see page 1718) For information about *OnReconcileError*, see Reconciling Update Errors. (see page 1737)

The following example shows how to provide feedback about the update status of records using the *UpdateStatus* method. It assumes that you have changed the *StatusFilter* property to include *usDeleted*, allowing deleted records to remain visible in the dataset. It further assumes that you have added a calculated field to the dataset called "Status."

```
procedure TForm1.ClientDataSet1CalcFields(DataSet: TDataSet);
begin
  with ClientDataSet1 do begin
    case UpdateStatus of
      usUnmodified: FieldByName('Status').AsString := '';
      usModified: FieldByName('Status').AsString := 'M';
      usInserted: FieldByName('Status').AsString := 'I';
      usDeleted: FieldByName('Status').AsString := 'D';
    end;
  end;
end;
void __fastcall TForm1::ClientDataSet1CalcFields(TDataSet *DataSet)
{
  switch (DataSet->UpdateStatus())
  {
    case usUnmodified:
      ClientDataSet1Status->Value = NULL; break;
    case usModified:
      ClientDataSet1Status->Value = "M"; break;
    case usInserted:
      ClientDataSet1Status->Value = "I"; break;
    case usDeleted:
      ClientDataSet1Status->Value = "D"; break;
  }
}
```

Overview of Using Cached Updates (see page 1723)

Updating Records (see page 1731)

Choosing the Type of Dataset for Caching Updates (see page 1711)

3.2.3.8.15 Intervening as Updates Are Applied

When a client dataset applies its updates, the provider determines how to handle writing the insertions, deletions, and modifications to the database server or source dataset. When you use *TClientDataSet* with an external provider component, you can use the properties and events of that provider to influence the way updates are applied. These are described in Responding to client update requests (see page 1808).

When the provider is internal, however, as it is for any client dataset associated with a data access mechanism, you can't set its properties or provide event handlers. As a result, the client dataset publishes one property and two events that let you influence how the internal provider applies updates.

- UpdateMode controls what fields are used to locate records in the SQL statements the provider generates for applying updates. *UpdateMode* is identical to the provider's *UpdateMode* property. For information on the provider's *UpdateMode* property, see Influencing how updates are applied (see page 1815).
- OnGetTableName lets you supply the provider with the name of the database table to which it should apply updates. This lets the provider generate the SQL statements for updates when it can't identify the database table from the stored procedure or query specified by *CommandText*. For example, if the query executes a multi-table join that only requires updates to a single table, supplying an *OnGetTableName* event handler allows the internal provider to correctly apply updates. An *OnGetTableName* event handler has three parameters: the internal provider component, the internal dataset that fetched the

data from the server, and a parameter to return the table name to use in the generated SQL.

- BeforeUpdateRecord occurs for every record in the delta packet. This event lets you make any last-minute changes before the record is inserted, deleted, or modified. It also provides a way for you to execute your own SQL statements to apply the update in cases where the provider can't generate correct SQL (for example, for multi-table joins where multiple tables must be updated.) A *BeforeUpdateRecord* event handler has five parameters: the internal provider component, the internal dataset that fetched the data from the server, a delta packet that is positioned on the record that is about to be updated, an indication of whether the update is an insertion, deletion, or modification, and a parameter that returns whether the event handler performed the update. The use of these is illustrated in the following event handler. For simplicity, the example assumes the SQL statements are available as global variables that only need field values:

```
procedure TForm1.SimpleDataSet1BeforeUpdateRecord(Sender: TObject;
  SourceDS: TDataSet; DeltaDS: TCustomClientDataSet; UpdateKind: TUpdateKind;
  var Applied Boolean);
var
 SQL: string;
 Connection: TSQLConnection;
begin
 Connection := (SourceDS as TSimpleDataSet).Connection;
 case UpdateKind of
 ukModify:
   begin
    { 1st dataset: update Fields[1], use Fields[0] in where clause }
     SQL := Format(UpdateStmt1, [DeltaDS.Fields[1].NewValue, DeltaDS.Fields[0].OldValue]);
     Connection.Execute(SQL, nil, nil);
    { 2nd dataset: update Fields[2], use Fields[3] in where clause }
     SQL := Format(UpdateStmt2, [DeltaDS.Fields[2].NewValue, DeltaDS.Fields[3].OldValue]);
     Connection.Execute(SQL, nil, nil);
   end;
 ukDelete:
   begin
    { 1st dataset: use Fields[0] in where clause }
     SQL := Format(DeleteStmt1, [DeltaDS.Fields[0].OldValue]);
     Connection.Execute(SQL, nil, nil);
    { 2nd dataset: use Fields[3] in where clause }
     SQL := Format(DeleteStmt2, [DeltaDS.Fields[3].OldValue]);
     Connection.Execute(SQL, nil, nil);
   end;
 ukInsert:
   begin
    { 1st dataset: values in Fields[0] and Fields[1] }
      SQL := Format(InsertStmt1, [DeltaDS.Fields[0].NewValue, DeltaDS.Fields[1].NewValue]);
     Connection.Execute(SQL, nil, nil);
    { 2nd dataset: values in Fields[2] and Fields[3] }
     SQL := Format(InsertStmt2, [DeltaDS.Fields[2].NewValue, DeltaDS.Fields[3].NewValue]);
     Connection.Execute(SQL, nil, nil);
   end;
 end;
 Applied := True;
end;
void __fastcall TForm1::SimpleDataSet1BeforeUpdateRecord(TObject *Sender,
   TDataSet *SourceDS, TCustomClientDataSet *DeltaDS, TUpdateKind UpdateKind, bool &Applied)
{
  TSQLConnection *pConn := (dynamic_cast<TSimpleDataSet *>(SourceDS)->Connection);
  char buffer[256];
  switch (UpdateKind)
  case ukModify:
    // 1st dataset: update Fields[1], use Fields[0] in where clause
    sprintf(buffer, UpdateStmt1, DeltaDS->Fields->Fields[1]->NewValue,
            DeltaDS->Fields->Fields[0]->OldValue);
    pConn->Execute(buffer, NULL, NULL);
    // 2nd dataset: update Fields[2], use Fields[3] in where clause
    sprintf(buffer, UpdateStmt2, DeltaDS->Fields->Fields[2]->NewValue,
            DeltaDS->Fields->Fields[3]->OldValue);
    pConn->Execute(buffer, NULL, NULL);
    break;
```

```
    case ukDelete:
      // 1st dataset: use Fields[0] in where clause
      sprintf(buffer, DeleteStmt1, DeltaDS->Fields->Fields[0]->OldValue);
      pConn->Execute(buffer, NULL, NULL);
      // 2nd dataset: use Fields[3] in where clause
      sprintf(buffer, DeleteStmt2, DeltaDS->Fields->Fields[3]->OldValue);
      pConn->Execute(buffer, NULL, NULL);
      break;
    case ukInsert:
      // 1st dataset: values in Fields[0] and Fields[1]
      sprintf(buffer, UpdateStmt1, DeltaDS->Fields->Fields[0]->NewValue,
              DeltaDS->Fields->Fields[1]->NewValue);
      pConn->Execute(buffer, NULL, NULL);
      // 2nd dataset: values in Fields[2] and Fields[3]
      sprintf(buffer, UpdateStmt2, DeltaDS->Fields->Fields[2]->NewValue,
              DeltaDS->Fields->Fields[3]->NewValue);
      pConn->Execute(buffer, NULL, NULL);
      break;
  }
```

3.2.3.8.16 Limiting Records with Parameters

If the client dataset is

- a *TClientDataSet* instance whose associated provider represents a *TTable* or *TSQLTable* component
- a *TSimpleDataSet or a TBDEClientDataSet* instance whose *CommandType* property is *ctTable*

then it can use the Params property to limit the records that it caches in memory. Each parameter represents a field value that must be matched before a record can be included in the client dataset's data. This works much like a filter, except that with a filter, the records are still cached in memory, but unavailable.

Each parameter name must match the name of a field. When using *TClientDataSet*, these are the names of fields in the *TTable* or *TSQLTable* component associated with the provider. When using *TSimpleDataSet* or *TBDEClientDataSet*, these are the names of fields in the table on the database server. The data in the client dataset then includes only those records whose values on the corresponding fields match the values assigned to the parameters.

For example, consider an application that displays the orders for a single customer. When the user identifies the customer, the client dataset sets its *Params* property to include a single parameter named CustID (or whatever field in the source table is called) whose value identifies the customer whose orders should be displayed. When the client dataset requests data from the source dataset (see page 1725), it passes this parameter value. The provider then sends only the records for the identified customer. This is more efficient than letting the provider send all the orders records to the client application and then filtering the records using the client dataset.

Sending Query or Stored Procedure Parameters (see page 1727)

Limiting What Records Appear (see page 1741)

3.2.3.8.17 Merging Changes into Data

When you edit the data in a client dataset, all edits to the data exist only in an in-memory change log. This log can be maintained separately from the data itself, although it is completely transparent to objects that use the client dataset. That is, controls that navigate the client dataset or display its data see a view of the data that includes the changes. If you do not want to back out of changes, however, you should merge the change log into the data of the client dataset by calling the MergeChangeLog method. *MergeChangeLog* overwrites records in *Data* with any changed field values in the change log.

After *MergeChangeLog* executes, Data contains a mix of existing data and any changes that were in the change log. This mix becomes the new *Data* baseline against which further changes can be made. *MergeChangeLog* clears the change log of all records and resets the ChangeCount property to *0*.

Warning: Do not call *MergeChangeLog* for client datasets that use a provider. In this case, call *ApplyUpdates* to write changes to the database. For more information, see Applying updates (see page 1711).

Note: It is also possible to merge changes into the data of a separate client dataset if that dataset originally provided the data in the *Data* property. To do this, you must use a dataset provider. For an example of how to do this, see Assigning data directly (see page 1738).

If you do not want to use the extended undo capabilities of the change log, you can set the client dataset's LogChanges property to *False*. When *LogChanges* is *False*, edits are automatically merged when you post records and there is no need to call *MergeChangeLog*.

3.2.3.8.18 Navigating Data in Client Datasets

If an application uses standard data-aware controls, then a user can navigate through a client dataset's records using the built-in behavior of those controls. You can also navigate programmatically through records using standard dataset methods such as *First*, *Last*, *Next*, and *Prior*. For more information about these methods, see Navigating datasets (see page 1634).

Unlike most datasets, client datasets can also position the cursor at a specific record in the dataset by using the RecNo property. Ordinarily an application uses *RecNo* to determine the record number of the current record. Client datasets can, however, set *RecNo* to a particular record number to make that record the current one.

3.2.3.8.19 Obtaining Aggregate Values

To get the value of a maintained aggregate, call the Value method of the *TAggregate* object that represents the aggregate. *Value* returns the maintained aggregate for the group that contains the current record of the client dataset.

When you are summarizing over the entire client dataset, you can call *Value* at any time to obtain the maintained aggregate. However, when you are summarizing over grouped information, you must be careful to ensure that the current record is in the

group whose summary you want. Because of this, it is a good idea to obtain aggregate values at clearly specified times, such as when you move to the first record of a group or when you move to the last record of a group. Use the GetGroupState method to determine where the current record falls within a group.

To display maintained aggregates in data-aware controls, use the Fields editor to create a persistent aggregate field component. When you specify an aggregate field in the Fields editor, the client dataset's Aggregates is automatically updated to include the appropriate aggregate specification. The AggFields property contains the new aggregated field component, and the FindField method returns it.

See Also

Specifying Aggregates (see page 1730)

Aggregating Over Groups of Records (see page 1710)

3.2.3.8.20 Overriding the Dataset On the Application Server

The client datasets that are associated with a particular data access mechanism use the CommandText and *Com*mandType properties to specify the data they represent. When using *TClientDataSet*, however, the data is specified by the source dataset, not the client dataset. Typically, this source dataset has a property that specifies an SQL statement to generate the data or the name of a database table or stored procedure.

If the provider allows, *TClientDataSet* can override the property on the source dataset that indicates what data it represents. That is, if the provider permits, the client dataset's CommandText property replaces the property on the provider's dataset that specifies what data it represents. This allows *TClientDataSet* to specify dynamically what data it wants to see.

By default, external provider components do not let client datasets use the *CommandText* value in this way. To allow *TClientDataSet* to use its *CommandText* property, you must add *poAllowCommandText* to the Options property of the provider. Otherwise, the value of *CommandText* is ignored.

Note: Never remove *poAllowCommandText* from the *Options* property of *TBDEClientDataSet* or *TIBClientDataSet*. The client dataset's *Options* property is forwarded to the internal provider, so removing *poAllowCommandText* prevents the client dataset from specifying what data to access.

The client dataset sends its *CommandText* string to the provider at two times:

- When the client dataset first opens. After it has retrieved the first data packet from the provider, the client dataset does not send *CommandText* when fetching subsequent data packets.
- When the client dataset sends an Execute command to provider.

To send an SQL command or to change a table or stored procedure name at any other time, you must explicitly use the *IAppServer* interface that is available as the AppServer property. This property represents the interface through which the client dataset communicates with its provider.

Refreshing Records (see page 1724)

Communicating with Providers Using Custom Events (see page 1712)

3.2.3.8.21 Overview of Using Cached Updates

To use cached updates, the following order of processes must occur in an application:

Indicate the data you want to edit. How you do this depends on the type of client dataset you are using:

- If you are using *TClientDataSet*, Specify the provider component (see page 1729) that represent the data you want to edit.
- If you are using a client dataset associated with a particular data access mechanism, you must
- Identify the database server by setting the *DBConnection* property to an appropriate connection component.
- Indicate what data you want to see by specifying the CommandText and *CommandType* properties. *CommandType* indicates whether *CommandText* is an SQL statement to execute, the name of a stored procedure, or the name of a table. If *CommandText* is a query or stored procedure, use the Params property to provide any input parameters.
- Optionally, use the Options property to indicate whether nested detail sets and BLOB data should be included in data packets or fetched separately, whether specific types of edits (insertions, modifications, or deletions) should be disabled, whether a single update can affect multiple server records, and whether the client dataset's records are refreshed when it applies updates. *Options* is identical to a provider's *Options* property. As a result, it allows you to set options that are not relevant or appropriate. For example, there is no reason to include *poIncFieldProps*, because the client dataset does not fetch its data from a dataset with persistent fields. Conversely, you do not want to exclude *poAllowCommandText*, which is included by default, because that would disable the *CommandText* property, which the client dataset uses to specify what data it wants. For information on the provider's *Options* property, see Setting options that influence the data packets (see page 1818).

Display and edit the data, permit insertion of new records, and support deletions of existing records. Both the original copy of each record and any edits to it are stored in memory.This process is described in Editing data (see page 1715).

Fetch additional records as necessary. By default, client datasets fetch all records and store them in memory. If a dataset contains many records or records with large BLOB fields, you may want to change this so that the client dataset fetches only enough records for display and re-fetches as needed. For details on how to control the record-fetching process, see Requesting data from the source dataset or document (see page 1725).

Optionally, refresh the records. As time passes, other users may modify the data on the database server. This can cause the client dataset's data to deviate more and more from the data on the server, increasing the chance of errors when you apply updates. To mitigate this problem, you can refresh records that have not already been edited. See Refreshing records (see page 1724) for details.

Apply the locally cached records to the database or cancel the updates. For each record written to the database, a *BeforeUpdateRecord* event is triggered. If an error occurs when writing an individual record to the database, an *OnUpdateError* event enables the application to correct the error, if possible, and continue updating. When updates are complete, all successfully applied updates are cleared from the local cache. For more information about applying updates to the database, see Updating records (see page 1731).

Instead of applying updates, an application can cancel the updates, emptying the change log without writing the changes to the database. You can cancel the updates by calling CancelUpdates method. All deleted records in the cache are undeleted, modified records revert to original values, and newly inserted record simply disappear.

Choosing the Type of Dataset for Caching Updates (see page 1711)

Updating Records (see page 1731)

Indicating What Records Are Modified (see page 1717)

3.2.3.8.22 Passing Parameters to the Source Dataset

Client datasets can pass parameters to the source dataset to specify what data they want provided in the data packets it sends. These parameters can specify

- Input parameter values for a query or stored procedure that is run on the application server (see page 1727)
- Field values that limit the records sent in data packets (see page 1720)

You can specify parameter values that your client dataset sends to the source dataset at design time or at runtime. At design time, select the client dataset and double-click the Params property in the **Object Inspector**. This brings up the collection editor, where you can add, delete, or rearrange parameters. By selecting a parameter in the collection editor, you can use the **Object Inspector** to edit the properties of that parameter.

At runtime, use the CreateParam method of the *Params* property to add parameters to your client dataset. *CreateParam* returns a parameter object, given a specified name, parameter type, and datatype. You can then use the properties of that parameter object to assign a value to the parameter.

For example, the following code adds an input parameter named CustNo with a value of 605:

```
with ClientDataSet1.Params.CreateParam(ftInteger, 'CustNo', ptInput) do
AsInteger := 605;
TParam *pParam = ClientDataSet1->Params->CreateParam(ftInteger, "CustNo", ptInput);
pParam->AsInteger = 605;
```

If the client dataset is not active, you can send the parameters to the application server and retrieve a data packet that reflects those parameter values simply by setting the *Active* property to *True*.

Note: You may want to initialize parameter values from the current settings on the source dataset. You can do this by right-clicking the client dataset and choosing Fetch Params at design time or calling the FetchParams method at runtime.

Communicating with Providers Using Custom Events (see page 1712)

Overriding the Dataset On the Application Server (see page 1722)

3.2.3.8.23 Refreshing Records

Client datasets work with an in-memory snapshot of the data from the source dataset. If the source dataset represents server data, then as time elapses other users may modify that data. The data in the client dataset becomes a less accurate picture of the underlying data.

Like any other dataset, client datasets have a Refresh method that updates its records to match the current values on the server. However, calling *Refresh* only works if there are no edits in the change log. Calling *Refresh* when there are unapplied edits results in an exception.

Client datasets can also update the data while leaving the change log intact. To do this, call the RefreshRecord method. Unlike the *Refresh* method, *RefreshRecord* updates only the current record in the client dataset. *RefreshRecord* changes the record value originally obtained from the provider but leaves any changes in the change log.

Warning: It is not always appropriate to call *RefreshRecord*. If the user's edits conflict with changes made to the underlying dataset by other users, calling *RefreshRecord* masks this conflict. When the client dataset applies its updates (see page 1711), no reconcile error occurs and the application can't resolve the conflict.

In order to avoid masking update errors, you may want to check that there are no pending updates before calling *RefreshRecord*. For example, the following *AfterScroll* refreshes the current record every time the user moves to a new record (ensuring the most up-to-date value), but only when it is safe to do so.:

```
procedure TForm1.ClientDataSet1AfterScroll(DataSet: TDataSet);
begin
if ClientDataSet1.UpdateStatus = usUnModified then
```

```
ClientDataSet1.RefreshRecord;
end;
void __fastcall TForm1::ClientDataSet1AfterScroll(TDataSet *DataSet)
{
  if (ClientDataSet1->UpdateStatus == usUnModified)
    ClientDataSet1->RefreshRecord();
}
```

3.2.3.8.24 Representing Calculated Values

As with any dataset, you can add calculated fields (see page 1872) to your client dataset. These are fields whose values you calculate dynamically, usually based on the values of other fields in the same record.

Client datasets, however, let you optimize when fields are calculated by using internally calculated fields (see page 1735).

You can also tell client datasets to create calculated values that summarize the data in several records using maintained aggregates (see page 1735).

3.2.3.8.25 Requesting Data from the Source Dataset or Document

Client datasets can control how they fetch their data packets from a provider. By default, they retrieve all records from the source dataset. This is true whether the source dataset and provider are internal components (as with *TBDEClientDataSet,TSimpleDataSet,* and *TIBClientDataSet*), or separate components that supply the data for *TClientDataSet*.

You can change how the client dataset fetches records using the *PacketRecords* and *FetchOnDemand* properties.

Incremental fetching

By changing the PacketRecords property, you can specify that the client dataset fetches data in smaller chunks. *PacketRecords* specifies either how many records to fetch at a time, or the type of records to return. By default, *PacketRecords* is set to *-1*, which means that all available records are fetched at once, either when the client dataset is first opened, or when the application

explicitly calls *GetNextPacket*. When *PacketRecords* is *-1*, then after the client dataset first fetches data, it never needs to fetch more data because it already has all available records.

To fetch records in small batches, set *PacketRecords* to the number of records to fetch. For example, the following statement sets the size of each data packet to ten records:

```
ClientDataSet1.PacketRecords := 10;
ClientDataSet1->PacketRecords = 10;
```

This process of fetching records in batches is called "incremental fetching". Client datasets use incremental fetching when *PacketRecords* is greater than zero.

To fetch each batch of records, the client dataset calls GetNextPacket. Newly fetched packets are appended to the end of the data already in the client dataset. *GetNextPacket* returns the number of records it fetches. If the return value is the same as *PacketRecords*, the end of available records was not encountered. If the return value is greater than *0* but less than *PacketRecords*, the last record was reached during the fetch operation. If *GetNextPacket* returns *0*, then there are no more records to fetch.

Warning: Incremental fetching does not work if you are fetching data from a remote provider on a stateless application server. See Supporting state information in remote data modules (see page 1540) for information on how to use incremental fetching with stateless remote data modules.

Note: You can also use *PacketRecords* to fetch metadata information about the source dataset. To retrieve metadata information, set *PacketRecords* to *0*.

Fetch-on-demand

Automatic fetching of records is controlled by the *FetchOnDemand property. When FetchOnDemand is True (the default), the client dataset automatically fetches records as needed. To prevent automatic fetching of records, set FetchOnDemand to False. When FetchOnDemand is False, the application must explicitly call GetNextPacket to fetch records.*

For example, Applications that need to represent extremely large read-only datasets can turn off FetchOnDemand to ensure that the client datasets do not try to load more data than can fit into memory. Between fetches, the client dataset frees its cache using the EmptyDataSet method. This approach, however, does not work well when the client must post updates to the server.

The provider controls whether the records in data packets include BLOB data and nested detail datasets. If the provider excludes this information from records, the FetchOnDemand property causes the client dataset to automatically fetch BLOB data and detail datasets on an as-needed basis. If FetchOnDemand is False, and the provider does not include BLOB data and detail datasets with records, you must explicitly call the FetchBlobs or FetchDetails method to retrieve this information.

3.2.3.8.26 Saving Changes

Client datasets use different mechanisms for incorporating changes from the change log, depending on whether the client

datasets stores its data in a file or represents data obtained through a provider. Whichever mechanism is used, the change log is automatically emptied when all updates have been incorporated.

File-based applications can simply merge the changes into the local cache represented by the *Data* property. They do not need to worry about resolving local edits with changes made by other users. To merge the change log into the *Data* property, call the *MergeChangeLog* method. Merging changes into data (see page 1720) describes this process.

You can't use *MergeChangeLog* if you are using the client dataset to cache updates or to represent the data from an external provider component. The information in the change log is required for resolving updated records with the data stored in the database (or source dataset). Instead, you call *ApplyUpdates*, which attempts to write the modifications to the database server or source dataset, and updates the *Data* property only when the modifications have been successfully committed. See Applying updates (see page 1711) for more information about this process.

See Also

Undoing Changes (see page 1730)

3.2.3.8.27 Sending Query or Stored Procedure Parameters

When the client dataset's *CommandType* property is *ctQuery* or *ctStoredProc*, or, if the client dataset is a *TClientDataSet* instance, when the associated provider represents the results of a query or stored procedure, you can use the Params property to specify parameter values. When the client dataset requests data from the source dataset (see page 1725) or uses its Execute method to run a query or stored procedure that does not return a dataset, it passes these parameter values along with the request for data or the execute command. When the provider receives these parameter values, it assigns them to its associated dataset. It then instructs the dataset to execute its query or stored procedure using these parameter values, and, if the client dataset requested data, begins providing data, starting with the first record in the result set.

Note: Parameter names should match the names of the corresponding parameters on the source dataset.

3.2.3.8.28 Setting Up a Simple Dataset

Setting up a simple dataset requires two essential steps. Set up:

1. The connection information.
2. The dataset information.

The following steps describe setting up a simple dataset in more detail.

To use TSimpleDataSet:

1. Place the *TSimpleDataSet* component in a data module or on a form. Set its Name property to a unique value appropriate to your application.
2. Identify the database server that contains the data. There are two ways to do this:

- If you have a named connection in the connections file, expand the *Connectionproperty and specify the ConnectionName value.*
- For greater control over connection properties, transaction support, login support, and the ability to use a single connection for more than one dataset, use a separate *TSQLConnection* component instead. Specify the *TSQLConnection* component as the value of the Connection property. For details on *TSQLConnection*, see Connecting to databases (see page 1506).

3. To indicate what data you want to fetch from the server, expand the DataSet property and set the appropriate values. There are three ways to fetch data from the server:

- Set CommandType to *ctQuery* and set CommandText to an SQL statement you want to execute on the server. This statement is typically a SELECT statement. Supply the values for any parameters using the Params property.
- Set CommandType to *ctStoredProc* and set CommandText to the name of the stored procedure you want to execute. Supply the values for any input parameters using the Params property.
- Set CommandType to *ctTable* and set CommandText to the name of the database tables whose records you want to use.

4. If the data is to be used with visual data controls, add a data source component to the form or data module, and set its *DataSet* property to the *TSimpleDataSet* object. The data source component forwards the data in the client dataset's in-memory cache to data-aware components for display. Connect data-aware components to the data source using their *DataSource* and *DataField* properties.
5. Activate the dataset by setting the *Active* property to *true* (or, at runtime, calling the *Open* method).
6. If you executed a stored procedure, use the Params property to retrieve any output parameters.
7. When the user has edited the data in the simple dataset, you can apply those edits back to the database server by calling the ApplyUpdates method. Resolve any update errors in an OnReconcileError event handler. For more information on applying updates, see Updating records (see page 1731).

When to Use TSimpleDataset (see page 1736)

3.2.3.8.29 Sorting and Indexing

Using indexes provides several benefits to your applications:

- They allow client datasets to locate data quickly.
- They let you apply ranges to limit the available records.
- They let your application set up relationships with other datasets such as lookup tables or master/detail forms.
- They specify the order in which records appear.

If a client dataset represents server data or uses an external provider, it inherits a default index and sort order based on the data it receives. The default index is called DEFAULT_ORDER. You can use this ordering, but you cannot change or delete the index.

In addition to the default index, the client dataset maintains a second index, called CHANGEINDEX, on the changed records stored in the change log (*Delta* property). CHANGEINDEX orders all records in the client dataset as they would appear if the changes specified in *Delta* were applied. CHANGEINDEX is based on the ordering inherited from DEFAULT_ORDER. As with DEFAULT_ORDER, you cannot change or delete the CHANGEINDEX index.

You can use other existing indexes, and you can create your own indexes. The following sections describe how to create and use indexes with client datasets:

- Adding a new index (see page 1709)
- Deleting and switching indexes (see page 1715)
- Using indexes to group data (see page 1734)

Note: You may also want to review the material on indexes in table type datasets, which also applies to client datasets. This material is in Using Indexes to search for records (see page 1615) and Limiting records with ranges (see page 1597).

3.2.3.8.30 Specifying a Provider

Unlike the client datasets that are associated with a data access mechanism, *TClientDataSet* has no internal provider component to package data or apply updates. If you want it to represent data from a source dataset or XML document, therefore, you must associated the client dataset with an external provider component.

The way you associate *TClientDataSet* with a provider depends on whether the provider is in the same application as the client dataset or on a remote application server running on another system.

Provider's location	How to associate TClientDataSet
The provider is in the same application as the client dataset	If the provider is in the same application as the client dataset, you can associate it with a provider by choosing a provider from the drop-down list for the ProviderName property in the **Object Inspector**. This works as long as the provider has the same Owner as the client dataset. (The client dataset and the provider have the same *Owner* if they are placed in the same form or data module.) To use a local provider that has a different *Owner*, you must form the association at runtime using the client dataset's SetProvider method If you think you may eventually scale up to a remote provider, or if you want to make calls directly to the *IAppServer* interface, you can also set the ConnectionBroker property to a TLocalConnection component. If you use *TLocalConnection*, the *TLocalConnection* instance manages the list of all providers that are local to the application, and handles the client dataset's *IAppServer* calls. If you do not use *TLocalConnection*, the application creates a hidden object that handles the *IAppServer* calls from the client dataset.
The provider is on a remote application server	If the provider is on a remote application server, then, in addition to the ProviderName property, you need to specify a component that connects the client dataset to the application server. There are two properties that can handle this task: RemoteServer, which specifies the name of a connection component from which to get a list of providers, or *ConnectionBroker, which specifies a centralized broker that provides an additional level of indirection between the client dataset and the connection component. The connection component and, if used, the connection broker, reside in the same data module as the client dataset. The connection component establishes and maintains a connection to an application server, sometimes called a "data broker." For more information, see The structure of the client application (see page 1543)* *At design time, after you specify RemoteServer or ConnectionBroker, you can select a provider from the drop-down list for the ProviderName property in the **Object Inspector**. This list includes both local providers (in the same form or data module) and remote providers that can be accessed through the connection component.*

Note: If the connection component is an instance of *TDCOMConnection*, the application server must be registered on the client machine.

At runtime, you can switch among available providers (both local and remote) by setting *ProviderName* in code.

Refreshing Records (see page 1724)

Communicating with Providers Using Custom Events (see page 1712)

Overriding the Dataset on the Application Server (see page 1722)

3.2.3.8.31 Specifying Aggregates

To specify that you want to calculate summaries over the records in a client dataset, use the Aggregates property. *Aggregates* is a collection of aggregate specifications (TAggregate). You can add aggregate specifications to your client dataset using the Collection Editor at design time, or using the Add method of *Aggregates* at runtime. If you want to create field components for the aggregates, create persistent fields for the aggregated values in the Fields Editor.

Note: When you create aggregated fields, the appropriate aggregate objects are added to the client dataset's *Aggregates* property automatically. Do not add them explicitly when creating aggregated persistent fields (see page 1856).

For each aggregate, the Expression property indicates the summary calculation it represents. *Expression* can contain a simple summary expression such as

```
Sum(Field1)
```

or a complex expression that combines information from several fields, such as

```
Sum(Qty * Price) - Sum(AmountPaid)
```

Aggregate expressions include one or more of the summary operators in the following table

Summary operators for maintained aggregates

Operator	Use
Sum	Totals the values for a numeric field or expression
Avg	Computes the average value for a numeric or date-time field or expression
Count	Specifies the number of non-blank values for a field or expression
Min	Indicates the minimum value for a string, numeric, or date-time field or expression
Max	Indicates the maximum value for a string, numeric, or date-time field or expression

The summary operators act on field values or on expressions built from field values using the same operators you use to create filters. (You can't nest summary operators, however.) You can create expressions by using operators on summarized values with other summarized values, or on summarized values and constants. However, you can't combine summarized values with field values, because such expressions are ambiguous (there is no indication of which record should supply the field value.) These rules are illustrated in the following expressions:

Sum(Qty * Price)	{legal -- summary of an expression on fields }
Max(Field1) - Max(Field2)	{legal -- expression on summaries }
Avg(DiscountRate) * 100	{legal -- expression of summary and constant }
Min(Sum(Field1))	{illegal -- nested summaries }
Count(Field1) - Field2	{illegal -- expression of summary and field }

3.2.3.8.32 Undoing Changes

Even though a record's original version remains unchanged in *Data*, each time a user edits a record, leaves it, and returns to it, the user sees the last changed version of the record. If a user or application edits a record a number of times, each changed version of the record is stored in the change log as a separate entry.

Storing each change to a record makes it possible to support multiple levels of undo operations should it be necessary to restore a record's previous state:

- To remove the last change to a record, call UndoLastChange. *UndoLastChange* takes a Boolean parameter, *FollowChange*, that indicates whether to reposition the cursor on the restored record (*True*), or to leave the cursor on the current record (*False*). If there are several changes to a record, each call to *UndoLastChange* removes another layer of edits. *UndoLastChange* returns a Boolean value indicating success or failure. If the removal occurs, *UndoLastChange* returns *True*. Use the ChangeCount property to check whether there are more changes to undo. *ChangeCount* indicates the number of changes stored in the change log.
- Instead of removing each layer of changes to a single record, you can remove them all at once. To remove all changes to a record, select the record, and call RevertRecord. *RevertRecord* removes any changes to the current record from the change log.
- To restore a deleted record, first set the StatusFilter property to [*usDeleted*], which makes the deleted records "visible." Next, navigate to the record you want to restore and call *RevertRecord*. Finally, restore the *StatusFilter* property to [*usModified*, *usInserted*, *usUnmodified*] so that the edited version of the dataset (now containing the restored record) is again visible.
- At any point during edits, you can save the current state of the change log using the SavePoint property. Reading *SavePoint* returns a marker into the current position in the change log. Later, if you want to undo all changes that occurred since you read the save point, set *SavePoint* to the value you read previously. Your application can obtain values for multiple save points. However, once you back up the change log to a save point, the values of all save points that your application read after that one are invalid.
- You can abandon all changes recorded in the change log by calling CancelUpdates. *CancelUpdates* clears the change log, effectively discarding all edits to all records. Be careful when you call *CancelUpdates*. After you call *CancelUpdates*, you cannot recover any changes that were in the log.

See Also

Saving Changes (see page 1726)

3.2.3.8.33 Updating Records

The contents of the change log are stored as a data packet in the client dataset's *Delta* property. To make the changes in *Delta* permanent, the client dataset must apply them to the database (or source dataset or XML document).

When a client applies updates to the server, the following steps occur:

1. The client application calls the ApplyUpdates method (see page 1711) of a client dataset object. This method passes the contents of the client dataset's *Delta* property to the (internal or external) provider. *Delta* is a data packet that contains a client dataset's updated, inserted, and deleted records.
2. The provider applies the updates, caching any problem records that it can't resolve itself. See Responding to client update requests (see page 1808) for details on how the provider applies updates.
3. The provider returns all unresolved records to the client dataset in a *Result* data packet. The *Result* data packet contains all records that were not updated. It also contains error information, such as error messages and error codes.
4. The client dataset attempts to reconcile update errors (see page 1737) returned in the *Result* data packet on a record-by-record basis.

Indicating What Records Are Modified (see page 1717)

Choosing the Type of Dataset for Caching Updates (see page 1711)

3.2.3.8.34 Using a Client Dataset to Cache Updates

By default, when you edit data in most datasets, every time you delete or post a record, the dataset generates a transaction, deletes or writes that record to the database server, and commits the transaction. If there is a problem writing changes to the

database, your application is notified immediately: the dataset raises an exception when you post the record.

If your dataset uses a remote database server, this approach can degrade performance due to network traffic between your application and the server every time you move to a new record after editing the current record. To minimize the network traffic, you may want to cache updates locally. When you cache updates, you application retrieves data from the database, caches and edits it locally, and then applies the cached updates to the database in a single transaction. When you cache updates, changes to a dataset (such as posting changes or deleting records) are stored locally instead of being written directly to the dataset's underlying table. When changes are complete, your application calls a method that writes the cached changes to the database and clears the cache.

Caching updates can minimize transaction times and reduce network traffic. However, cached data is local to your application and is not under transaction control. This means that while you are working on your local, in-memory, copy of the data, other applications can be changing the data in the underlying database table. They also can't see any changes you make until you apply the cached updates. Because of this, cached updates may not be appropriate for applications that work with volatile data, as you may create or encounter too many conflicts when trying to merge your changes into the database.

Although the BDE and ADO provide alternate mechanisms for caching updates, using a client dataset for caching updates has several advantages:

- Applying updates when datasets are linked in master/detail relationships is handled for you. This ensures that updates to multiple linked datasets are applied in the correct order.
- Client datasets give you the maximum of control over the update process. You can set properties to influence the SQL that is generated for updating records, specify the table to use when updating records from a multi-table join, or even apply updates manually from a *BeforeUpdateRecord* event handler.
- When errors occur applying cached updates to the database server, only client datasets (and dataset providers) provide you with information about the current record value on the database server in addition to the original (unedited) value from your dataset and the new (edited) value of the update that failed.
- Client datasets let you specify the number of update errors you want to tolerate before the entire update is rolled back.

The following topics describe in more detail on how to use a client dataset to cache updates:

- Overview of using cached updates (see page 1723).
- Choosing the type of dataset for caching updates (see page 1711).
- Indicating what records are modified (see page 1717).
- Updating records (see page 1731).

Using a Client Dataset with Flat File Data (see page 1733)

3.2.3.8.35 Using a Client Dataset with a Provider

A client dataset uses a provider to supply it with data and apply updates when

- It caches updates from a database server or another dataset.
- It represents the data in an XML document.
- It stores the data in the client portion of a multi-tiered application.

For any client dataset other than *TClientDataSet*, this provider is internal, and so not directly accessible by the application. With *TClientDataSet*, the provider is an external component that links the client dataset to an external source of data.

An external provider component can reside in the same application as the client dataset, or it can be part of a separate application running on another system. For more information about provider components, see Using Provider Components (

see page 1819). For more information about applications where the provider is in a separate application on another system, see Creating multi-tiered applications (see page 1518).

When using an (internal or external) provider, the client dataset always caches any updates. For information on how this works, see Using a client dataset to cache updates (see page 1731).

The following topics describe additional properties and methods of the client dataset that enable it to work with a provider:

- Specifying a provider (see page 1729)
- Requesting data from the source dataset or document (see page 1725).
- Getting Parameters From the Application Server (see page 1715)
- Passing parameters to the source dataset (see page 1723)
- Handling constraints from the server (see page 1716)
- Refreshing records (see page 1724).
- Communicating with providers using custom events (see page 1712)
- Overriding the source dataset (see page 1722)

Using a Client Dataset to Cache Updates (see page 1731)

Using a Client Dataset with Flat File Data (see page 1733)

Creating Multi-tiered Applications (see page 1518)

3.2.3.8.36 Using a Client Dataset with File-based Data

Client datasets can work with dedicated files on disk as well as server data. This allows them to be used in file-based database applications (see page 1564) and "briefcase model" applications (see page 1565). The special files that client datasets use for their data are called MyBase.

Tip: All client datasets are appropriate for a briefcase model application, but for a pure MyBase application (one that does not use a provider), it is preferable to use *TClientDataSet*, because it involves less overhead.

In a pure MyBase application, the client application cannot get table definitions and data from the server, and there is no server to which it can apply updates. Instead, the client dataset must independently

- Define and create tables (see page 1714)
- Load saved data (see page 1739)
- Merge edits into its data (see page 1720)
- Save data (see page 1740)

Using a Client Dataset to Cache Updates (see page 1731)

Using a Client Dataset with a Provider (see page 1732)

3.2.3.8.37 Using a Simple Dataset

TSimpleDataSet is a special type of client dataset designed for simple two-tiered applications. Like a unidirectional dataset, it can use an SQL connection component to connect to a database server and specify an SQL statement to execute on that

server. Like other client datasets, it buffers data in memory to allow full navigation and editing support.

TSimpleDataSet works the same way as a generic client dataset (*TClientDataSet*) that is linked to a unidirectional dataset by a dataset provider. In fact, *TSimpleDataSet* has its own, internal provider, which it uses to communicate with an internally created unidirectional dataset.

Using a simple dataset can simplify the process of two-tiered application development because you don't need to work with as many components.

When to use TSimpleDataSet (see page 1736) provides information on when and how to use a simple dataset:

See Also

Copying Data from Another Dataset (see page 1714)

Using a Client Dataset with File-based Data (see page 1733)

Using a Client Dataset with a Provider (see page 1732)

Using a Client Dataset to Buffer Records (see page 1559)

3.2.3.8.38 Using Indexes to Group Data

When you use an index in your client dataset, it automatically imposes a sort order on the records. Because of this order, adjacent records usually contain duplicate values on the fields that make up the index. For example, consider the following fragment from an orders table that is indexed on the SalesRep and Customer fields:

SalesRep	Customer	OrderNo	Amount
1	1	5	100
1	1	2	50
1	2	3	200
1	2	6	75
2	1	1	10
2	3	4	200

Because of the sort order, adjacent values in the SalesRep column are duplicated. Within the records for SalesRep 1, adjacent values in the Customer column are duplicated. That is, the data is grouped by SalesRep, and within the SalesRep group it is grouped by Customer. Each grouping has an associated level. In this case, the SalesRep group has level 1 (because it is not nested in any other groups) and the Customer group has level 2 (because it is nested in the group with level 1). Grouping level corresponds to the order of fields in the index.

Client datasets let you determine where the current record lies within any given grouping level. This allows your application to display records differently, depending on whether they are the first record in the group, in the middle of a group, or the last record in a group. For example, you might want to display a field value only if it is on the first record of the group, eliminating the duplicate values. To do this with the previous table results in the following:

SalesRep	Customer	OrderNo	Amount
1	1	5	100
		2	50
	2	3	200
		6	75
2	1	1	10

	3	4	200

To determine where the current record falls within any group, use the GetGroupState method. *GetGroupState* takes an integer giving the level of the group and returns a value indicating where the current record falls the group (first record, last record, or neither).

When you create an index, you can specify the level of grouping it supports (up to the number of fields in the index). *GetGroupState* can't provide information about groups beyond that level, even if the index sorts records on additional fields.

See Also

Adding a New Index (see page 1709)

Using Maintained Aggregates (see page 1735)

Deleting and Switching Indexes (see page 1715)

3.2.3.8.39 Using Internally Calculated Fields in Client Datasets

In other datasets, your application must compute the value of calculated fields every time the record changes or the user edits any fields in the current record. It does this in an OnCalcFields event handler.

While you can still do this, client datasets let you minimize the number of times calculated fields must be recomputed by saving calculated values in the client dataset's data. When calculated values are saved with the client dataset, they must still be recomputed when the user edits the current record, but your application need not recompute values every time the current record changes. To save calculated values in the client dataset's data, use internally calculated fields instead of calculated fields.

Internally calculated fields, just like calculated fields, are calculated in an *OnC*alcFields event handler. However, you can optimize your event handler by checking the State property of your client dataset. When *State* is *dsInternalCalc*, you must recompute internally calculated fields. When *State* is *dsCalcFields*, you need only recompute regular calculated fields.

To use internally calculated fields, you must define the fields as internally calculated before you create the client dataset (see page 1587). Depending on whether you use persistent fields or field definitions, you do this in one of the following ways:

- If you use persistent fields, define fields as internally calculated by selecting InternalCalc in the Fields editor.
- If you use field definitions, set the InternalCalcField property of the relevant field definition to *True*.

  Note: Other types of datasets use internally calculated fields. However, with other datasets, you do not calculate these values in an *OnCalcFields* event handler. Instead, they are computed automatically by the BDE or remote database server.

See Also

Using Maintained Aggregates (see page 1735)

Defining a Calculated Field (see page 1872)

Programming a Calculated Field (see page 1870)

3.2.3.8.40 Using Maintained Aggregates

Client datasets provide support for summarizing data over groups of records. Because these summaries are automatically updated as you edit the data in the dataset, this summarized data is called a "maintained aggregate."

In their simplest form, maintained aggregates let you obtain information such as the sum of all values in a column of the client dataset. They are flexible enough, however, to support a variety of summary calculations and to provide subtotals over groups of records defined by a field in an index that supports grouping (see page 1734).

The following topics describe how to

- Specify aggregates (see page 1730).
- Aggregate Over Groups of Records (see page 1710).
- Obtain aggregate values (see page 1721).

See Also

Using Internally Calculated Fields in Client Datasets (see page 1735)

Using Indexes to Group Data (see page 1734)

3.2.3.8.41 When to Use TSimpleDataSet

TSimpleDataSet is intended for use in a simple two-tiered database applications and briefcase model applications. It provides an easy-to-set up component for linking to the database server, fetching data, caching updates, and applying them back to the server. It can be used in most two-tiered applications.

There are times, however, when it is more appropriate to use *TClientDataSet*:

- If you are not using data from a database server (for example, if you are using a dedicated file on disk (see page 1564)), then *TClientDataSet* has the advantage of less overhead.
- Only *TClientDataSet* can be used in a multi-tiered database application . Thus, if you are writing a multi-tiered application, or if you intend to scale up to a multi-tiered application eventually, you should use *TClientDataSet* with an external provider and source dataset.
- Because the source dataset is internal to the simple dataset component, you can't link two source datasets in a master/detail relationship to obtain nested detail sets. (You can, however, link two simple datasets into a master/detail relationship.)
- The simple dataset does not surface any of the events or properties that occur on its internal dataset provider. However, in most cases, these events are used in multi-tiered applications, and are not needed for two-tiered applications.

Setting up a simple dataset (see page 1727) provides information on setting up a simple dataset:

See Also

Setting Up a Simple Dataset (see page 1727)

3.2.3.8.42 Cloning a Client Dataset Cursor

Client datasets use the *CloneCursor* method to let you work with a second view of the data at runtime. *CloneCursor* lets a second client dataset share the original client dataset's data. This is less expensive than copying all the original data, but, because the data is shared, the second client dataset can't modify the data without affecting the original client dataset.

CloneCursor takes three parameters: *Source* specifies the client dataset to clone. The last two parameters (*Reset* and *KeepSettings*) indicate whether to copy information other than the data. This information includes any filters, the current index, links to a master table (when the source dataset is a detail set), the *ReadOnly* property, and any links to a connection component or provider.

When *Reset* and *KeepSettings* are *False*, a cloned client dataset is opened, and the settings of the source client dataset are used to set the properties of the destination. When *Reset* is *True*, the destination dataset's properties are given the default values (no index or filters, no master table, *ReadOnly* is *False*, and no connection component or provider is specified). When *KeepSettings* is *True*, the destination dataset's properties are not changed.

3.2.3.8.43 Working with Data Using a Client Dataset

Like any dataset, you can use client datasets to supply the data for data-aware controls using a data source component. See Using data controls (see page 1778) for information on how to display database information in data-aware controls.

Client datasets implement all the properties an methods inherited from *TDataSet*. For a complete introduction to this generic dataset behavior, see Understanding datasets (see page 1632).

In addition, client datasets implement many of the features common to table type datasets (see page 1620) such as

- Sorting records with indexes (see page 1609).
- Using Indexes to search for records (see page 1615).
- Limiting records with ranges (see page 1597).
- Creating master/detail relationships (see page 1590).
- Controlling read/write access (see page 1587)
- Creating the underlying dataset (see page 1587)
- Emptying the dataset (see page 1592)
- Synchronizing client datasets (see page 1614)

Client datasets differ from other datasets in that they hold all their data in memory. Because of this, their support for some database functions can involve additional capabilities or considerations. The following topics describe some of these common functions and the differences introduced by client datasets:

- Navigating data (see page 1721)
- Limiting What Records Appear (see page 1741)
- Editing data (see page 1715) .
- Constraining data values (see page 1713)
- Sorting and indexing (see page 1728) .
- Representing calculated values (see page 1725) .
- Copying data from another dataset (see page 1714).
- Adding application-specific information to the data (see page 1709) .

Using a Client Dataset with a Provider (see page 1732)

Using a Client Dataset with Flat File Data (see page 1733)

3.2.3.8.44 Reconciling Update Errors

There are two events that let you handle errors that occur during the update process:

- During the update process, the internal provider generates an OnUpdateError event every time it encounters an update that it can't handle. If you correct the problem in an *OnUpdateError* event handler, then the error does not count toward the maximum number of errors passed to the *ApplyUpdates* method. This event only occurs for client datasets that use an internal provider. If you are using *TClientDataSet*, you can use the provider component's *OnUpdateError* event instead.
- After the entire update operation is finished, the client dataset generates an OnReconcileError event for every record that the provider could not apply to the database server.

You should always code an *OnReconcileError* or *OnUpdateError* event handler, even if only to discard the records returned that could not be applied. The event handlers for these two events work the same way. They include the following parameters:

DataSet: A client dataset that contains the updated record which couldn't be applied. You can use this dataset's methods to get information about the problem record and to edit the record in order to correct any problems. In particular, you will want to use the CurValue, OldValue, and NewValue properties of the fields in the current record to determine the cause of the update problem. However, you must not call any client dataset methods that change the current record in your event handler.

E: An object that represents the problem that occurred. You can use this exception to extract an error message or to determine the cause of the update error.

UpdateKind: The type of update that generated the error. *UpdateKind* can be *ukModify* (the problem occurred updating an existing record that was modified), *ukInsert* (the problem occurred inserting a new record), or *ukDelete* (the problem occurred deleting an existing record).

Action: A **var** parameter that indicates what action to take when the event handler exits. In your event handler, you set this parameter to

- Skip this record, leaving it in the change log. (rrSkip or raSkip)
- Stop the entire reconcile operation. (rrAbort or raAbort)
- Merge the modification that failed into the corresponding record from the server. (rrMerge or raMerge) This only works if the server record does not include any changes to fields modified in the client dataset's record.
- Replace the current update in the change log with the value of the record in the event handler, which has presumably been corrected. (rrApply or raCorrect)
- Ignore the error completely. (rrIgnore) This possibility only exists in the *OnUpdateError* event handler, and is intended for the case where the event handler applies the update back to the database server. The updated record is removed from the change log and merged into *Data*, as if the provider had applied the update.
- Back out the changes for this record on the client dataset, reverting to the originally provided values. (raCancel) This possibility only exists in the *OnReconcileError* event handler.
- Update the current record value to match the record on the server. (raRefresh) This possibility only exists in the *OnReconcileError* event handler.

The following code shows an *OnReconcileError* event handler that uses the reconcile error dialog from the RecError unit which ships in the objrepos directory. (To use this dialog, add RecError to your uses clause.)

```
procedure TForm1.ClientDataSetReconcileError(DataSet: TCustomClientDataSet; E:
EReconcileError; UpdateKind: TUpdateKind, var Action TReconcileAction);
begin
  Action := HandleReconcileError(DataSet, UpdateKind, E);
end;
void __fastcall TForm1::ClientDataSetReconcileError(TCustomClientDataSet *DataSet,
    EReconcileError *E, TUpdateKind UpdateKind, TReconcileAction &Action)
{
  Action = HandleReconcileError(this, DataSet, UpdateKind, E);
}
```

Intervening as Updates Are Applied (see page 1718)

3.2.3.8.45 Assigning Data Directly

You can use the client dataset's *Data* property to assign data to a client dataset from another dataset. *Data* is a data packet in the form of an OleVariant. A data packet can come from another client dataset or from any other dataset by using a provider. Once a data packet is assigned to *Data*, its contents are displayed automatically in data-aware controls connected to the client dataset by a data source component.

When you open a client dataset that represents server data or that uses an external provider component, data packets are automatically assigned to *Data*.

When your client dataset does not use a provider, you can copy the data from another client dataset as follows:

```
ClientDataSet1.Data := ClientDataSet2.Data;
ClientDataSet1->Data = ClientDataSet2->Data;
```

Note: When you copy the *Data* property of another client dataset, you copy the change log as well, but the copy does not reflect any filters or ranges that have been applied. To include filters or ranges, you must clone the source dataset's cursor instead.

If you are copying from a dataset other than a client dataset, you can create a dataset provider component, link it to the source dataset, and then copy its data:

```
TempProvider := TDataSetProvider.Create(Form1);
TempProvider.DataSet := SourceDataSet;
ClientDataSet1.Data := TempProvider.Data;
TempProvider.Free;
TempProvider = new TDataSetProvider(Form1);
TempProvider->DataSet = SourceDataSet;
ClientDataSet1->Data = TempProvider->Data;
delete TempProvider;
```

Note: When you assign directly to the *Data* property, the new data packet is not merged into the existing data. Instead, all previous data is replaced.

If you want to merge changes from another dataset, rather than copying its data, you must use a provider component. Create a dataset provider as in the previous example, but attach it to the destination dataset and instead of copying the data property, use the *ApplyUpdates* method:

```
TempProvider := TDataSetProvider.Create(Form1);
TempProvider.DataSet := ClientDataSet1;
TempProvider.ApplyUpdates(SourceDataSet.Delta, -1, ErrCount);
TempProvider.Free;
TempProvider = new TDataSetProvider(Form1);
TempProvider->DataSet = ClientDataSet1;
TempProvider->ApplyUpdates(SourceDataSet->Delta, -1, ErrCount);
delete TempProvider;
```

Editing Data (see page 1715)

3.2.3.8.46 Loading Data from a File or Stream

To load data from a file, call a client dataset's LoadFromFile method. *LoadFromFile* takes one parameter, a string that specifies the file from which to read data. The file name can be a fully qualified path name, if appropriate. If you always load the client dataset's data from the same file, you can use the FileName property instead. If *FileName* names an existing file, the data is automatically loaded when the client dataset is opened.

To load data from a stream, call the client dataset's *LoadFromStream* method. *LoadFromStream* takes one parameter, a stream object that supplies the data.

The data loaded by *LoadFromFile* (*LoadFromStream)* must have previously been saved in a client dataset's data format by this or another client dataset using the *SaveToFile* (SaveToStream) method, or generated from an XML document. For more information about saving data to a file or stream, see Saving data to a file or stream (see page 1740). For information about creating client dataset data from an XML document, see Using XML in database applications (see page 1847).

When you call *LoadFromFile* or *LoadFromStream*, all data in the file is read into the *Data* property. Any edits that were in the change log when the data was saved are read into the *Delta* property. However, the only indexes that are read from the file are those that were created with the dataset.

Saving Data to a File or Stream (see page 1740)

3.2.3.8.47 Saving Data to a File or Stream

Even when you have merged changes into the data of a client dataset, this data still exists only in memory. While it persists if you close the client dataset and reopen it in your application, it will disappear when your application shuts down. To make the data permanent, it must be written to disk. Write changes to disk using the SaveToFile method.

SaveToFile takes one parameter, a string that specifies the file into which to write data. The file name can be a fully qualified path name, if appropriate. If the file already exists, its current contents are completely overwritten.

Note: *SaveToFile* does not preserve any indexes you added to the client dataset at runtime, only indexes that were added when you created the client dataset.

If you always save the data to the same file, you can use the FileName *property instead. If FileName is set, the data is automatically saved to the named file when the client dataset is closed.*

You can also save data to a stream, using the SaveToStream method. SaveToStream takes one parameter, a stream object that receives the data.

Note: *If you save a client dataset while there are still edits in the change log, these are not merged with the data. When you reload the data, using the LoadFromFile or LoadFromStream method, the change log will still contain the unmerged edits. This is important for applications that support the briefcase model, where those changes will eventually have to be applied to a provider component on the application server.*

3.2.3.8.48 Using Client Datasets: Overview

Client datasets are specialized datasets that hold all their data in memory. The support for manipulating the data they store in memory is provided by midaslib.dcu or midas.dll. The format client datasets use for storing data is self-contained and easily transported, which allows client datasets to

- Read from and write to dedicated files on disk, acting as a file-based dataset. Properties and methods supporting this mechanism are described in Using a client dataset with file-based data (see page 1733).
- Cache updates for data from a database server. Client dataset features that support cached updates are described in Using a client dataset to cache updates (see page 1731).
- Represent the data in the client portion of a multi-tiered application. To function in this way, the client dataset must work with an external provider, as described in Using a client dataset with a provider (see page 1732). For information about multi-tiered database applications, see Creating multi-tiered applications (see page 1518).
- Represent the data from a source other than a dataset. Because a client dataset can use the data from an external provider, specialized providers can adapt a variety of information sources to work with client datasets. For example, you can use an XML provider to enable a client dataset to represent the information in an XML document.

Whether you use client datasets for file-based data, caching updates, data from an external provider (such as working with an XML document or in a multi-tiered application), or a combination of these approaches such as a "briefcase model" application, you can take advantage of broad range of features client datasets support for working with data (see page 1737).

3.2.3.8.49 Limiting What Records Appear

To restrict users to a subset of available data on a temporary basis, applications can use ranges and filters. When you apply a range or a filter, the client dataset does not display all the data in its in-memory cache. Instead, it only displays the data that meets the range or filter conditions. For more information about using filters, see Displaying and editing a subset of data using filters (see page 1631). For more information about ranges, see Limiting records with ranges (see page 1597).

With most datasets, filter strings are parsed into SQL commands that are then implemented on the database server. Because of this, the SQL dialect of the server limits what operations are used in filter strings. Client datasets implement their own filter support, which includes more operations than that of other datasets. For example, when using a client dataset, filter expressions can include string operators that return substrings, operators that parse date/time values, and much more. Client datasets also allow filters on BLOB fields or complex field types such as ADT fields and array fields.

The various operators and functions that client datasets can use in filters, along with a comparison to other datasets that support filters, is given below:

Filter support in client datasets

Operator or function	Example	Supported by other datasets	Comment
Comparisons			
=	State = 'CA'	Yes	
<>	State <> 'CA'	Yes	
>=	DateEntered >= '1/1/1998'	Yes	
<=	Total <= 100,000	Yes	
>	Percentile > 50	Yes	

<	Field1 < Field2	Yes	
BLANK	State <> 'CA' or State = BLANK	Yes	Blank records do not appear unless explicitly included in the filter.
IS NULL	Field1 IS NULL	No	
IS NOT NULL	Field1 IS NOT NULL	No	
Logical operators			
and	State = 'CA' and Country = 'US'	Yes	
or	State = 'CA' or State = 'MA'	Yes	
not	not (State = 'CA')	Yes	
Arithmetic operators			
+	Total + 5 > 100	Depends on driver	Applies to numbers, strings, or date (time) + number.
-	Field1 - 7 <> 10	Depends on driver	Applies to numbers, dates, or date (time) - number.
*	Discount * 100 > 20	Depends on driver	Applies to numbers only.
/	Discount > Total / 5	Depends on driver	Applies to numbers only.
String functions			
Upper	Upper(Field1) = 'ALWAYS'	No	
Lower	Lower(Field1 + Field2) = 'josp'	No	
Substring	Substring(DateFld,8) = '1998' Substring(DateFld,1,3) = 'JAN'	No	Value goes from position of second argument to end or number of chars in third argument. First char has position 1.
Trim	Trim(Field1 + Field2) Trim(Field1, '-')	No	Removes third argument from front and back. If no third argument, trims spaces.
TrimLeft	TrimLeft(StringField) TrimLeft(Field1, '$') <> ''	No	See Trim.
TrimRight	TrimRight(StringField) TrimRight(Field1, '.') <> ''	No	See Trim.
DateTime functions			
Year	Year(DateField) = 2000	No	
Month	Month(DateField) <> 12	No	
Day	Day(DateField) = 1	No	
Hour	Hour(DateField) < 16	No	
Minute	Minute(DateField) = 0	No	
Second	Second(DateField) = 30	No	
GetDate	GetDate - DateField > 7	No	Represents current date and time.
Date	DateField = Date(GetDate)	No	Returns the date portion of a datetime value.

Time	TimeField > Time(GetDate)	No	Returns the time portion of a datetime value.
Miscellaneous			
Like	Memo LIKE '%filters%'	No	Works like SQL-92 without the ESC clause. When applied to BLOB fields, FilterOptions determines whether case is considered.
In	Day(DateField) in (1,7)	No	Works like SQL-92. Second argument is a list of values all with the same type.
*	State = 'M*'	Yes	Wildcard for partial comparisons.

When applying ranges or filters, the client dataset still stores all of its records in memory. The range or filter merely determines which records are available to controls that navigate or display data from the client dataset.

Note: When fetching data from a provider, you can also limit the data that the client dataset stores by supplying parameters to the provider. For details, see Limiting Records with Parameters (see page 1720).

3.2.3.9 Using data controls

Topics

Name	Description
Associating a Data Control with a Dataset (see page 1746)	Data controls connect to datasets by using a data source. A data source component (TDataSource) acts as a conduit between the control and a dataset containing data. Each data-aware control must be associated with a data source component to have data to display and manipulate. Similarly, all datasets must be associated with a data source component in order for their data to be displayed and manipulated in data-aware controls on a form. **Note:** Data source components are also required for linking unnested datasets in master-detail relationships.
Choosing How to Organize the Data (see page 1747)	When you build the user interface for your database application, you have choices to make about how you want to organize the display of information and the controls that manipulate that information. One of the first decisions to make is whether you want to display a single record at a time, or multiple records (see page 1760). In addition, you will want to add controls to navigate and manipulate records (see page 1767). The TDBNavigator control provides built-in support for many of the functions you may want to perform.
Changing the Associated Dataset at Runtime (see page 1747)	In Associating a Data Control with a Dataset (see page 1746), the datasource was associated with its dataset by setting the *DataSet* property at design time. At runtime, you can switch the dataset for a data source component as needed. For example, the following code swaps the dataset for the *CustSource* data source component between the dataset components named *Customers* and *Orders*:

Restricting Field Values with Radio Controls (see page 1748)	TDBRadioGroup is a data-aware version of a radio group control. It enables you to set the value of a data field with a radio button control where there is a limited number of possible values for the field. The radio group includes one button for each value a field can accept. Users can set the value for a data field by selecting the desired radio button. The *Items property determines the radio buttons that appear in the group. Items is a string list. One radio button is displayed for each string in Items, and each string appears to the... more (see page 1748)*
Disabling and Enabling Data Display (see page 1768)	When your application iterates through a dataset or performs a search, you should temporarily prevent refreshing of the values displayed in data-aware controls each time the current record changes. Preventing refreshing of values speeds the iteration or search and prevents annoying screen-flicker. *DisableControls is a dataset method that disables display for all data-aware controls linked to a dataset. As soon as the iteration or search is over, your application should immediately call the dataset's EnableControls method to re-enable display for the controls.* *Usually you disable controls before entering an iterative process. The iterative process itself should take place inside a... more (see page 1768)*
Displaying and Editing Data in List and Combo Boxes (see page 1768)	There are four data controls that provide the user with a set of default data values to choose from at runtime. These are data-aware versions of standard list and combo box controls: • TDBListBox, which displays a scrollable list of items from which a user can choose to enter in a data field. A data-aware list box displays a default value for a field in the current record and highlights its corresponding entry in the list. If the current row's field value is not in the list, no value is highlighted in the list box. When a user selects a list... more (see page 1768)
Displaying and Editing Data in Lookup List and Combo Boxes (see page 1769)	Lookup list boxes and lookup combo boxes (TDBLookupListBox and TDBLookupComboBox) present the user with a restricted list of choices from which to set a valid field value. When a user selects a list item, the corresponding field value is changed in the underlying dataset. For example, consider an order form whose fields are tied to the *OrdersTable*. *OrdersTable* contains a *CustNo* field corresponding to a customer ID, but *OrdersTable* does not have any other customer information. The *CustomersTable*, on the other hand, contains a *CustNo* field corresponding to a customer ID, and also contains additional information, such as... more (see page 1769)
Displaying and Editing Fields in an Edit Box (see page 1770)	TDBEdit is a data-aware version of an edit box component. *TDBEdit* displays the current value of a data field to which it is linked and permits it to be edited using standard edit box techniques. For example, suppose *CustomersSource* is a *TDataSource* component that is active and linked to an open TClientDataSet called *CustomersTable*. You can then place a *TDBEdit* component on a form and set its properties as follows: • *DataSource*: CustomersSource • *DataField*: CustNo The data-aware edit box component immediately displays the value of the current row of the *CustNo* column of the *CustomersTable* dataset, both at... more (see page 1770)
Displaying and Editing Graphics Fields in an Image Control (see page 1771)	TDBImage is a data-aware control that displays graphics contained in BLOB fields. By default, *TDBImage* permits a user to edit a graphics image by cutting and pasting to and from the Clipboard using the CutToClipboard, CopyToClipboard, and PasteFromClipboard methods. You can, instead, supply your own editing methods attached to the event handlers for the control. By default, an image control displays as much of a graphic as fits in the control, cropping the image if it is too big. You can set the *Stretch property to True to resize the graphic to fit within an image control as it is... more (see page 1771)*

Displaying and Editing Text in a Memo Control (see page 1771)	TDBMemo is a data-aware component—similar to the standard TMemo component—that can display lengthy text data. *TDBMemo* displays multi-line text, and permits a user to enter multi-line text as well. You can use *TDBMemo* controls to display large text fields or text data contained in binary large object (BLOB) fields. By default, *TDBMemo* permits a user to edit memo text. To prevent editing, set the *ReadOnly property of the memo control to True. To display tabs and permit users to enter them in a memo, set the WantTabs property to True. To limit the number of characters users can... more (see page 1771)*
Displaying and Editing Text in a Rich Edit Memo Control (see page 1772)	TDBRichEdit is a data-aware component—similar to the standard *TRichEdit* component—that can display formatted text stored in a binary large object (BLOB) field. *TDBRichEdit* displays formatted, multi-line text, and permits a user to enter formatted multi-line text as well. **Note:** While *TDBRichEdit* provides properties and methods to enter and work with rich text, it does not provide any user interface components to make these formatting options available to the user. Your application must implement the user interface to surface rich text capabilities. By default, *TDBRichEdit* permits a user to edit memo text. To prevent editing, set the *ReadOnly property of the... more (see page 1772)*
Displaying Data as Labels (see page 1772)	TDBText is a read-only control similar to the TLabel component on the Standard category of the **Tool palette**. A *TDBText* control is useful when you want to provide display-only data on a form that allows user input in other controls. For example, suppose a form is created around the fields in a customer list table, and that once the user enters a street address, city, and state or province information in the form, you use a dynamic lookup to automatically determine the zip code field from a separate table. A *TDBText* component tied to the zip code table could... more (see page 1772)
Editing and Updating Data (see page 1773)	All data controls except the navigator display data from a database field. In addition, you can use them to edit and update data as long as the underlying dataset allows it. **Note:** Unidirectional datasets never permit users to edit and update data. The following topics describe how to allow users to edit data using data controls: • Enabling Editing in Controls On User Entry (see page 1774) • Editing Data in a Control (see page 1773)
Editing Data in a Control (see page 1773)	A data control can only post edits to its associated dataset if the dataset's CanModify property is *True*. *CanModify* is always *False* for unidirectional datasets. Some datasets have a *ReadOnly* property that lets you specify whether *CanModify* is *True*. **Note:** Whether a dataset can update data depends on whether the underlying database table permits updates. Even if the dataset's *CanModify* property is *True*, the Enabled property of the data source that connects the dataset to the control must be *True* as well before the control can post updates back to the database table. The *Enabled* property of... more (see page 1773)
Enabling and Disabling the Data Source (see page 1774)	The data source has an Enabled property that determines if it is connected to its dataset. When *Enabled* is *True*, the data source is connected to a dataset. You can temporarily disconnect a single data source from its dataset by setting *Enabled* to *False*. When *Enabled* is *False*, all data controls attached to the data source component go blank and become inactive until *Enabled* is set to *True*. It is recommended, however, to control access to a dataset through a dataset component's DisableControls and EnableControls methods because they affect all attached data sources.
Enabling Editing in Controls On User Entry (see page 1774)	A dataset must be in *dsEdit* state to permit editing to its data. If the data source's AutoEdit property is *True* (the default), the data control handles the task of putting the dataset into *dsEdit* mode as soon as the user tries to edit its data. If *AutoEdit* is *False*, you must provide an alternate mechanism for putting the dataset into edit mode. One such mechanism is to use a TDBNavigator control with an *Edit* button, which lets users explicitly put the dataset into edit mode. For more information about *TDBNavigator*, see Navigating and manipulating records (see page 1767). Alternately,... more (see page 1774)
Enabling Mouse, Keyboard, and Timer Events (see page 1774)	The Enabled property of a data control determines whether it responds to mouse, keyboard, or timer events, and passes information to its data source. The default setting for this property is *True*. To prevent mouse, keyboard, or timer events from reaching a data control, set its *Enabled* property to *False*. When *Enabled* is *False*, the data source that connects the control to its dataset does not receive information from the data control. The data control continues to display data, but the text displayed in the control is dimmed.

Handling Boolean Field Values with Check Boxes (see page 1775)	TDBCheckBox is a data-aware check box control. It can be used to set the values of Boolean fields in a dataset. For example, a customer invoice form might have a check box control that when checked indicates the customer is tax-exempt, and when unchecked indicates that the customer is not tax-exempt. The data-aware check box control manages its checked or unchecked state by comparing the value of the current field to the contents of ValueChecked and ValueUnchecked properties. If the field value matches the *ValueChecked* property, the control is checked. Otherwise, if the field matches the *ValueUnchecked* property, the control... more (see page 1775)
Refreshing Data Display (see page 1776)	The Refresh method for a dataset flushes local buffers and re-fetches data for an open dataset. You can use this method to update the display in data-aware controls if you think that the underlying data has changed because other applications have simultaneous access to the data used in your application. If you are using cached updates, before you refresh the dataset you must apply any updates the dataset has currently cached. Refreshing can sometimes lead to unexpected results. For example, if a user is viewing a record deleted by another application, then the record disappears the moment your application calls... more (see page 1776)
Responding to Changes Mediated by the Data Source (see page 1776)	Because the data source provides the link between the data control and its dataset, it mediates all of the communication that occurs between the two. Typically, the data-aware control automatically responds to changes in the dataset. However, if your user interface is using controls that are not data-aware, you can use the events of a data source component to manually provide the same sort of response. The OnDataChange event occurs whenever the data in a record may have changed, including field edits or when the cursor moves to a new record. This event is useful for making sure the control... more (see page 1776)
Using Common Data Control Features (see page 1777)	The following tasks are common to most data controls: • Associating a data control with a dataset (see page 1746) • Editing and updating data (see page 1773) • Disabling and enabling data display (see page 1768) • Refreshing data display (see page 1776) • Enabling mouse (see page 1774) Data controls let you display and edit fields of data associated with the current record in a dataset. The following table summarizes the data controls that appear on the Data Controls category of the **Tool palette**. ***Data controls***
Using TDBListBox and TDBComboBox (see page 1778)	When using *TDBListBox* or *TDBComboBox*, you must use the String List editor at design time to create the list of items to display. To bring up the String List editor, click the ellipsis button for the *Items property in the **Object Inspector**. Then type in the items that you want to have appear in the list. At runtime, use the methods of the Items property to manipulate its string list.* *When a TDBListBox or TDBComboBox control is linked to a field through its DataField property, the field value appears selected in the list. If the current value is... more (see page 1778)*
Using Data Controls (see page 1778)	The Data Controls category of the **Tool palette** provides a set of data-aware controls that represent data from fields in a database record, and, if the dataset allows it, enable users to edit that data and post changes back to the database. By placing data controls onto the forms in your database application, you can build your database application's user interface (UI) so that information is visible and accessible to users. The data-aware controls you add to your user interface depend on several factors, including the following: • The type of data you are displaying. You can choose between controls... more (see page 1778)

3.2.3.9.1 Associating a Data Control with a Dataset

Data controls connect to datasets by using a data source. A data source component (TDataSource) acts as a conduit between

the control and a dataset containing data. Each data-aware control must be associated with a data source component to have data to display and manipulate. Similarly, all datasets must be associated with a data source component in order for their data to be displayed and manipulated in data-aware controls on a form.

Note: Data source components are also required for linking unnested datasets in master-detail relationships.

To associate a data control with a dataset

1. Place a dataset in a data module (or on a form), and set its properties as appropriate.
2. Place a data source in the same data module (or form). Using the **Object Inspector**, set its DataSet property to the dataset you placed in step 1.
3. Place a data control from the Data Access category of the **Tool palette** onto a form.
4. Using the **Object Inspector**, set the *DataSource* property of the control to the data source component you placed in step 2.
5. Set the *DataField* property of the control to the name of a field to display, or select a field name from the drop-down list for the property. This step does not apply to *TDBGrid, TDBCtrlGrid,* and *TDBNavigator* because they access all available fields in the dataset.
6. Set the *Active* property of the dataset to *True* to display data in the control.

For more information about managing the link between the data control and its dataset, see

- Changing the Associated Dataset at Runtime (see page 1747)
- Enabling and Disabling the Data Source (see page 1774)
- Responding to Changes Mediated by the Data Source (see page 1776)

Editing and Updating Data (see page 1773)

Disabling and Enabling Data Display (see page 1768)

Refreshing Data Display (see page 1776)

Enabling Mouse (see page 1774)

3.2.3.9.2 Choosing How to Organize the Data

When you build the user interface for your database application, you have choices to make about how you want to organize the display of information and the controls that manipulate that information.

One of the first decisions to make is whether you want to display a single record at a time, or multiple records (see page 1760).

In addition, you will want to add controls to navigate and manipulate records (see page 1767). The TDBNavigator control provides built-in support for many of the functions you may want to perform.

See Also

Using Common Data Control Features (see page 1777)

Navigating and Manipulating Records (see page 1767)

3.2.3.9.3 Changing the Associated Dataset at Runtime

In Associating a Data Control with a Dataset (see page 1746), the datasource was associated with its dataset by setting the *DataSet* property at design time. At runtime, you can switch the dataset for a data source component as needed. For example, the following code swaps the dataset for the *CustSource* data source component between the dataset components named *Customers* and *Orders*:

```
with CustSource do begin
  if (DataSet = Customers) then
    DataSet := Orders
  else
    DataSet := Customers;
end;
if (CustSource->DataSet == Customers)
  CustSource->DataSet = Orders;
else
  CustSource->DataSet = Customers;
```

You can also set the *DataSet* property to a dataset on another form to synchronize the data controls on two forms. For example:

```
procedure TForm2.FormCreate (Sender : TObject);
begin
  DataSource1.Dataset := Form1.Table1;
end;
void __fastcall TForm2::FormCreate(TObject *Sender)
{
  DataSource1->DataSet = Form1->Table1;
}
```

Enabling and Disabling the Data Source (see page 1774)

Responding to Changes Mediated by the Data Source (see page 1776)

3.2.3.9.4 Restricting Field Values with Radio Controls

TDBRadioGroup is a data-aware version of a radio group control. It enables you to set the value of a data field with a radio button control where there is a limited number of possible values for the field. The radio group includes one button for each value a field can accept. Users can set the value for a data field by selecting the desired radio button.

The *Items property determines the radio buttons that appear in the group. Items is a string list. One radio button is displayed for each string in Items, and each string appears to the right of a radio button as the button's label.*

If the current value of a field associated with a radio group matches one of the strings in the Items property, that radio button is selected. For example, if three strings, "Red," "Yellow," and "Blue," are listed for Items, and the field for the current record contains the value "Blue," then the third button in the group appears selected.

***Note:** If the field does not match any strings in Items, a radio button may still be selected if the field matches a string in the Values property. If the field for the current record does not match any strings in Items or Values, no radio button is selected.*

The Values property can contain an optional list of strings that can be returned to the dataset when a user selects a radio button and posts a record. Strings are associated with buttons in numeric sequence. The first string is associated with the first button, the second string with the second button, and so on. For example, suppose Items contains "Red," "Yellow," and "Blue," and Values contains "Magenta," "Yellow," and "Cyan." If a user selects the button labeled "Red," "Magenta" is posted to the database.

If strings for Values are not provided, the Item string for a selected radio button is returned to the database when a record is posted.

Topics

Name	Description
Arranging the Order of Persistent Columns (see page 1751)	The order in which columns appear in the Columns editor is the same as the order the columns appear in the grid. You can change the column order by dragging and dropping columns within the Columns list box.
Choosing Navigator Buttons to Display (see page 1752)	When you first place a TDBNavigator on a form at design time, all its buttons are visible. You can use the VisibleButtons property to turn off buttons you do not want to use on a form. For example, when working with a unidirectional dataset, only the *First*, *Next*, and *Refresh* buttons are meaningful. On a form that is intended for browsing rather than editing, you might want to disable the *Edit*, *Insert*, *Delete*, *Post*, and *Cancel* buttons.

Controlling Grid Drawing (see page 1753)	Your first level of control over how a grid control draws itself is setting column properties. The grid automatically uses the font, color, and alignment properties of a column to draw the cells of that column. The text of data fields is drawn using the *DisplayFormat* or *EditFormat properties of the field component associated with the column.* *You can augment the default grid display logic with code in a grid's OnDrawColumnCell event. If the grid's DefaultDrawing property is True, all the normal drawing is performed before your OnDrawColumnCell event handler is called. Your code can then draw on top of... more (see page 1753)*
Creating a Customized Grid (see page 1754)	A customized grid is one for which you define persistent column objects that describe how a column appears and how the data in the column is displayed. A customized grid lets you configure multiple grids to present different views of the same dataset (different column orders, different field choices, and different column colors and fonts, for example). A customized grid also enables you to let users modify the appearance of the grid at runtime without affecting the fields used by the grid or the field order of the dataset. Customized grids are best used with datasets whose structure is known... more (see page 1754)
Creating a Grid That Contains Other Data-aware Controls (see page 1755)	A TDBCtrlGrid control displays multiple fields in multiple records in a tabular grid format. Each cell in a grid displays multiple fields from a single row.
Creating Persistent Columns (see page 1756)	To customize the appearance of grid at design time, you invoke the Columns editor to create a set of persistent column objects for the grid. At runtime, the State property for a grid with persistent column objects is automatically set to *csCustomized*.
Defining a Lookup List Column (see page 1757)	You can create a column that displays a drop-down list of values, similar to a lookup combo box control (see page 1769). To specify that the column acts like a combo box, set the column's *ButtonStyle property to cbsAuto. Once you populate the list with values, the grid automatically displays a combo box-like drop-down button when a cell of that column is in edit mode.* *There are two ways to populate that list with the values for users to select:* • You can fetch the values from a lookup table. To make a column display a drop-down list of values drawn from... more (see page 1757)
Deleting Persistent Columns (see page 1757)	Deleting a persistent column from a grid is useful for eliminating fields that you do not want to display.
Displaying ADT and Array Fields (see page 1758)	Sometimes the fields of the grid's dataset do not represent simple values such as text, graphics, numerical values, and so on. Some database servers allow fields that are a composite of simpler data types, such as ADT fields or array fields. There are two ways a grid can display composite fields: • It can "flatten out" the field so that each of the simpler types that make up the field appears as a separate field in the dataset. • It can display composite fields in a single column, reflecting the fact that they are a single field. When a composite field is... more (see page 1758)
Displaying Fly-over Help (see page 1759)	To display fly-over help for each navigator button at runtime, set the navigator ShowHint property to True. When *ShowHint* is True, the navigator displays fly-by Help hints whenever you pass the mouse cursor over the navigator buttons. *ShowHint* is *False* by default. The Hints property controls the fly-over help text for each button. By default *Hints* is an empty string list. When *Hints* is empty, each navigator button displays default help text. To provide customized fly-over help for the navigator buttons, use the String list editor to enter a separate line of hint text for each button in the *Hints... more (see page 1759)*
Displaying Multiple Records (see page 1760)	Sometimes you want to display many records in the same form. For example, an invoicing application might show all the orders made by a single customer on the same form. To display multiple records, use a grid control. Grid controls provide a multi-field, multi-record view of data that can make your application's user interface more compelling and effective. They are discussed in Viewing and editing data with TDBGrid (see page 1766) and Creating a grid that contains other data-aware controls (see page 1755). **Note:** You can't display multiple records when using a unidirectional dataset. You may want to design a user interface that displays both... more (see page 1760)

Editing in the Grid (see page 1760)	At runtime, you can use a grid to modify existing data and enter new records, if the following default conditions are met: • The CanModify property of the *Dataset* is *True*. • The ReadOnly property of grid is *False*. When a user edits a record in the grid, changes to each field are posted to an internal record buffer, but are not posted until the user moves to a different record in the grid. Even if focus is changed to another control on a form, the grid does not post changes until another the cursor for the dataset is moved... more (see page 1760)
Putting a Button in a Column (see page 1761)	A column can display an ellipsis button (...) to the right of the normal cell editor. `Ctrl+Enter` or a mouse click fires the grid's OnEditButtonClick event. You can use the ellipsis button to bring up forms containing more detailed views of the data in the column. For example, in a table that displays summaries of invoices, you could set up an ellipsis button in the invoice total column to bring up a form that displays the items in that invoice, or the tax calculation method, and so on. For graphic fields, you could use the ellipsis button to bring up... more (see page 1761)
Responding to User Actions at Runtime (see page 1761)	You can modify grid behavior by writing event handlers to respond to specific actions within the grid at runtime. Because a grid typically displays many fields and records at once, you may have very specific needs to respond to changes to individual columns. For example, you might want to activate and deactivate a button elsewhere on the form every time a user enters and exits a specific column. The following table lists the grid events available in the **Object Inspector**. ***Grid control events***
Restoring Default Values to a Column (see page 1762)	At runtime you can test a column's AssignedValues property to determine whether a column property has been explicitly assigned. Values that are not explicitly defined are dynamically based on the associated field or the grid's defaults. You can undo property changes made to one or more columns. In the Columns editor, select the column or columns to restore, and then select Restore Defaults from the context menu. Restore defaults discards assigned property settings and restores a column's properties to those derived from its underlying field component At runtime, you can reset all default properties for a single column by calling... more (see page 1762)
Setting Column Properties at Design Time (see page 1763)	Column properties determine how data is displayed in the cells of that column. Most column properties obtain their default values from properties associated with another component (called the *default source*) such as a grid or an associated field component. To set a column's properties, select the column in The Columns editor and set its properties in the **Object Inspector**. The following table summarizes key column properties you can set. ***Column properties***
Setting Grid Options (see page 1764)	You can use the grid Options property at design time to control basic grid behavior and appearance at runtime. When a grid component is first placed on a form at design time, the *Options* property in the **Object Inspector** is displayed with a + (plus) sign to indicate that the *Options* property can be expanded to display a series of Boolean properties that you can set individually. To view and set these properties, click on the + sign. The list of options in the **Object Inspector** below the *Options* property. The + sign changes to a –(minus) sign, that collapses... more (see page 1764)
Using a Grid Control in Its Default State (see page 1765)	The *Stateproperty of the grid's Columns property indicates whether persistent column objects exist for the grid. Columns.State is a runtime-only property that is automatically set for a grid. The default state is csDefault, meaning that persistent column objects do not exist for the grid. In that case, the display of data in the grid is determined primarily by the properties of the fields in the grid's dataset, or, if there are no persistent field components, by a default set of display characteristics.* *When the grid's Columns.State property is csDefault, grid columns are dynamically generated from the visible... more (see page 1765)*

Using a Single Navigator for Multiple Datasets (see page 1766)	As with other data-aware controls, a navigator's *DataSource property specifies the data source that links the control to a dataset. By changing a navigator's DataSource property at runtime, a single navigator can provide record navigation and manipulation for multiple datasets.* *Suppose a form contains two edit controls linked to the CustomersTable and OrdersTable datasets through the CustomersSource and OrdersSource data sources respectively. When a user enters the edit control connected to CustomersSource, the navigator should also use CustomersSource, and when the user enters the edit control connected to OrdersSource, the navigator should switch to OrdersSource as well.... more (see page 1766)*
Viewing and Editing Data with TDBGrid (see page 1766)	A TDBGrid control lets you view and edit records in a dataset in a tabular grid format. Three factors affect the appearance of records displayed in a grid control: • Existence of persistent column objects defined for the grid using the Columns editor. Persistent column objects provide great flexibility setting grid and data appearance. For information on using persistent columns, see Creating a customized grid (see page 1754). • Creation of persistent field components for the dataset displayed in the grid. For more information about creating persistent field components using the Fields editor, see Working with field components (see page 1877). • The dataset's *ObjectView* property setting... more (see page 1766)
Navigating and Manipulating Records (see page 1767)	TDBNavigator provides users a simple control for navigating through records in a dataset, and for manipulating records. The navigator consists of a series of buttons that enable a user to scroll forward or backward through records one at a time, go to the first record, go to the last record, insert a new record, update an existing record, post data changes, cancel data changes, delete a record, and refresh record display. The following figure shows the navigator that appears by default when you place it on a form at design time. The navigator consists of a series of buttons that... more (see page 1767)

3.2.3.9.4.1 Arranging the Order of Persistent Columns

The order in which columns appear in the Columns editor is the same as the order the columns appear in the grid. You can change the column order by dragging and dropping columns within the Columns list box.

To change the order of a column

1. Select the column in the Columns list box.
2. Drag it to a new location in the list box.

You can also change the column order at runtime by clicking on the column title and dragging the column to a new position.

Note: Reordering persistent fields in the Fields editor also reorders columns in a default grid, but not a custom grid.

Warning: You cannot reorder columns in grids containing both dynamic columns and dynamic fields at design time, since there is nothing persistent to record the altered field or column order.

At runtime, a user can use the mouse to drag a column to a new location in the grid if its DragMode property is set to *dmManual*. Reordering the columns of a grid with a *State* property of *csDefault* state also reorders field components in the dataset underlying the grid. The order of fields in the physical table is not affected. To prevent a user from rearranging columns at runtime, set the grid's *DragMode* property to *dmAutomatic*.

At runtime, the grid's *OnColumnMoved event fires after a column has been moved.*

Restoring Default Values to a Column (see page 1762)

3.2.3.9.4.2 Choosing Navigator Buttons to Display

When you first place a TDBNavigator on a form at design time, all its buttons are visible. You can use the VisibleButtons property to turn off buttons you do not want to use on a form. For example, when working with a unidirectional dataset, only the *First*, *Next*, and *Refresh* buttons are meaningful. On a form that is intended for browsing rather than editing, you might want to disable the *Edit*, *Insert*, *Delete*, *Post*, and *Cancel* buttons.

Hiding and showing navigator buttons at design time

The VisibleButtons property in the **Object Inspector** is displayed with a + sign to indicate that it can be expanded to display a Boolean value for each button on the navigator. To view and set these values, click on the + sign. The list of buttons that can be turned on or off appears in the **Object Inspector** below the *VisibleButtons* property. The + sign changes to a –(minus) sign, which you can click to collapse the list of properties.

Button visibility is indicated by the *Boolean* state of the button value. If a value is set to *True*, the button appears in the TDBNavigator. If *False*, the button is removed from the navigator at design time and runtime.

Note: As button values are set to *False*, they are removed from the TDBNavigator on the form, and the remaining buttons are expanded in width to fill the control. You can drag the control's handles to resize the buttons.

Hiding and showing navigator buttons at runtime

At runtime you can hide or show navigator buttons in response to user actions or application states. For example, suppose you provide a single navigator for navigating through two different datasets, one of which permits users to edit records, and the other of which is read-only. When you switch between datasets, you want to hide the navigator's *Insert*, *Delete*, *Edit*, *Post*, *Cancel*, and *Refresh* buttons for the read-only dataset, and show them for the other dataset.

For example, suppose you want to prevent edits to the *OrdersTable* by hiding the *Insert*, *Delete*, *Edit*, *Post*, *Cancel*, and *Refresh* buttons on the navigator, but that you also want to allow editing for the *CustomersTable*. The VisibleButtons property controls which buttons are displayed in the navigator. Here's one way you might code the event handler:

```
procedure TForm1.CustomerCompanyEnter(Sender :TObject);
begin
  if Sender = CustomerCompany then
  begin
    DBNavigatorAll.DataSource := CustomerCompany.DataSource;
    DBNavigatorAll.VisibleButtons := [nbFirst,nbPrior,nbNext,nbLast];
  end
```

```
  else
  begin
    DBNavigatorAll.DataSource := OrderNum.DataSource;
    DBNavigatorAll.VisibleButtons := DBNavigatorAll.VisibleButtons + [nbInsert,
      nbDelete,nbEdit,nbPost,nbCancel,nbRefresh];
  end;
end;
```

For a C++ example, suppose you want to prevent edits to the OrdersTable by hiding the Insert, Delete, Edit, Post, Cancel, and Refresh buttons on the navigator, but that you also want to allow editing for the CustomersTable. The VisibleButtons property controls which buttons are displayed in the navigator. Here's one way you might code the event handler:

```
void __fastcall TForm1::CustomerCompanyEnter(TObject *Sender)
{
  if (Sender == (TObject *)CustomerCompany)
  {
    DBNavigatorAll->DataSource = CustomerCompany->DataSource;
    DBNavigatorAll->VisibleButtons = DBNavigatorAll->VisibleButtons
<< nbFirst << nbPrior << nbNext << nbLast;
  }
  else
  {
    DBNavigatorAll->DataSource = OrderNum->DataSource;
    DBNavigatorAll->VisibleButtons = DBNavigatorAll->VisibleButtons << nbInsert
<< nbDelete << nbEdit
<< nbPost << nbCancel << nbRefresh;
  }
}
```

Using a Single Navigator for Multiple Datasets (see page 1766)

3.2.3.9.4.3 Controlling Grid Drawing

Your first level of control over how a grid control draws itself is setting column properties. The grid automatically uses the font, color, and alignment properties of a column to draw the cells of that column. The text of data fields is drawn using the *DisplayFormat* or *EditFormat properties of the field component associated with the column.*

You can augment the default grid display logic with code in a grid's OnDrawColumnCell event. If the grid's DefaultDrawing property is True, all the normal drawing is performed before your OnDrawColumnCell event handler is called. Your code can then draw on top of the default display. This is primarily useful when you have defined a blank persistent column and want to draw special graphics in that column's cells.

If you want to replace the drawing logic of the grid entirely, set DefaultDrawing to False and place your drawing code in the grid's OnDrawColumnCell event. If you want to replace the drawing logic only in certain columns or for certain field data types, you can call the DefaultDrawColumnCell inside your OnDrawColumnCell event handler to have the grid use its normal drawing code for selected columns. This reduces the amount of work you have to do if you only want to change the way Boolean field types are drawn, for example.

Using a Grid Control in Its Default State (see page 1765)

Creating a Customized Grid (see page 1754)

Creating Persistent Columns (see page 1756)

Setting Grid Options (see page 1764)

Editing in the Grid (see page 1760)

Responding to User Actions at Runtime (see page 1761)

Displaying ADT and Array Fields (see page 1758)

3.2.3.9.4.4 Creating a Customized Grid

A customized grid is one for which you define persistent column objects that describe how a column appears and how the data in the column is displayed. A customized grid lets you configure multiple grids to present different views of the same dataset (different column orders, different field choices, and different column colors and fonts, for example). A customized grid also enables you to let users modify the appearance of the grid at runtime without affecting the fields used by the grid or the field order of the dataset.

Customized grids are best used with datasets whose structure is known at design time. Because they expect field names established at design time to exist in the dataset, customized grids are not well suited to browsing arbitrary tables selected at runtime.

Understanding persistent columns

When you create persistent column objects for a grid, they are only loosely associated with underlying fields in a grid's dataset. Default property values for persistent columns are dynamically fetched from a default source (the associated field or the grid itself) until a value is assigned to the column property. Until you assign a column property a value, its value changes as its default source changes. Once you assign a value to a column property, it no longer changes when its default source changes.

For example, the default source for a column title caption is an associated field's DisplayLabel property. If you modify the *DisplayLabelproperty, the column title reflects that change immediately. If you then assign a string to the column title's caption, the tile caption becomes independent of the associated field's DisplayLabel property. Subsequent changes to the field's DisplayLabel property no longer affect the column's title.*

Persistent columns exist independently from field components with which they are associated. In fact, persistent columns do not have to be associated with field objects at all. If a persistent column's FieldName property is blank, or if the field name does not match the name of any field in the grid's current dataset, the column's Field property is NULL and the column is drawn with blank cells. If you override the cell's default drawing method, you can display your own custom information in the blank cells. For example, you can use a blank column to display aggregated values on the last record of a group of records that the aggregate summarizes. Another possibility is to display a bitmap or bar chart that graphically depicts some aspect of the record's data.

Two or more persistent columns can be associated with the same field in a dataset. For example, you might display a part number field at the left and right extremes of a wide grid to make it easier to find the part number without having to scroll the grid.

***Note:** Because persistent columns do not have to be associated with a field in a dataset, and because multiple columns can reference the same field, a customized grid's FieldCount property can be less than or equal to the grid's column count. Also note that if the currently selected column in a customized grid is not associated with a field, the grid's SelectedField property is NULL and the SelectedIndexproperty is –1.*

Persistent columns can be configured to display grid cells as a combo box drop-down list of lookup values from another dataset or from a static pick list, or as an ellipsis button (...) in a cell that can be clicked upon to launch special data viewers or dialogs related to the current cell.

The following topics provide additional information about persistent columns:

- Creating Persistent Columns (see page 1756)
- Deleting Persistent Columns (see page 1757)
- Arranging the Order of Persistent Columns (see page 1751)
- Setting Column Properties at Design Time (see page 1763)
- Defining a Lookup List Column (see page 1757)
- Putting a Button in a Column (see page 1761)

- Restoring Default Values to a Column (see page 1762)

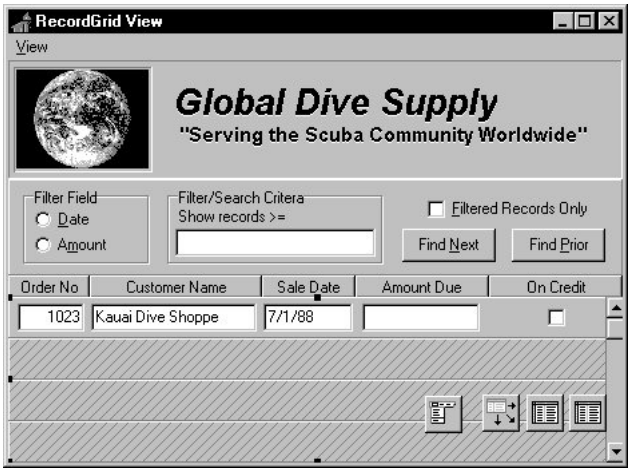
Controlling Grid Drawing (see page 1753)

Responding to User Actions at Runtime (see page 1761)



3.2.3.9.4.5 Creating a Grid That Contains Other Data-aware Controls

A TDBCtrlGrid control displays multiple fields in multiple records in a tabular grid format. Each cell in a grid displays multiple fields from a single row.

To use a database control grid

1. Place a database control grid on a form.
2. Set the grid's DataSource property to the name of a data source.
3. Place individual data controls within the design cell for the grid. The design cell for the grid is the top or leftmost cell in the grid, and is the only cell into which you can place other controls.
4. Set the *DataField* property for each data control to the name of a field. The data source for these data controls is already set to the data source of the database control grid.
5. Arrange the controls within the cell as desired.

When you compile and run an application containing a database control grid, the arrangement of data controls you set in the design cell at runtime is replicated in each cell of the grid. Each cell displays a different record in a dataset.

The following table summarizes some of the unique properties for database control grids that you can set at design time:

Selected database control grid properties

Property	Purpose
AllowDelete	*True* (default): Permits record deletion. *False*: Prevents record deletion.

AllowInsert	*True* (default): Permits record insertion. *False*: Prevents record insertion.
ColCount	Sets the number of columns in the grid. Default = 1.
Orientation	*goVertical* (default): Display records from top to bottom. *goHorizontal*: Displays records from left to right.
PanelHeight	Sets the height for an individual panel. Default = 72.
PanelWidth	Sets the width for an individual panel. Default = 200.
RowCount	Sets the number of panels to display. Default = 3.
ShowFocus	*True* (default): Displays a focus rectangle around the current record's panel at runtime. *False*: Does not display a focus rectangle.

Viewing and Editing Data with TDBGrid (see page 1766)

3.2.3.9.4.6 Creating Persistent Columns

To customize the appearance of grid at design time, you invoke the Columns editor to create a set of persistent column objects for the grid. At runtime, the State property for a grid with persistent column objects is automatically set to *csCustomized*.

To create persistent columns for a grid control

1. Select the grid component in the form.
2. Invoke the Columns editor by double clicking on the grid's *Columns property in the* ***Object Inspector****.*

The Columns list box displays the persistent columns that have been defined for the selected grid. When you first bring up the Columns editor, this list is empty because the grid is in its default state, containing only dynamic columns.

You can create persistent columns for all fields in a dataset at once, or you can create persistent columns on an individual basis.

To create persistent columns for all fields

1. Right-click the grid to invoke the context menu and choose Add All Fields. Note that if the grid is not already associated with a data source, Add All Fields is disabled. Associate the grid with a data source that has an active dataset before choosing Add All Fields.
2. If the grid already contains persistent columns, a dialog box asks if you want to delete the existing columns, or append to the column set. If you choose Yes, any existing persistent column information is removed, and all fields in the current dataset are inserted by field name according to their order in the dataset. If you choose No, any existing persistent column information is retained, and new column information, based on any additional fields in the dataset, are appended to the dataset.
3. Click Close to apply the persistent columns to the grid and close the dialog box.

To create persistent columns individually

1. Choose the Add button in the Columns editor. The new column will be selected in the list box. The new column is given a sequential number and default name (for example, 0 - TColumn).
2. To associate a field with this new column, set the FieldName property in the **Object Inspector**.
3. To set the title for the new column, expand the Title property in the **Object Inspector** and set its *Caption* property.
4. Close the Columns editor to apply the persistent columns to the grid and close the dialog box.

At runtime, you can switch to persistent columns by assigning *csCustomized* to the *Columns.State* property. Any existing columns in the grid are destroyed and new persistent columns are built for each field in the grid's dataset. You can then add a persistent column at runtime by calling the *Add* method for the column list:

```
DBGrid1.Columns.Add;
```

```
DBGrid1->Columns->Add();
```

Setting Column Properties at Design Time (see page 1763)

Restoring Default Values to a Column (see page 1762)

3.2.3.9.4.7 Defining a Lookup List Column

You can create a column that displays a drop-down list of values, similar to a lookup combo box control (see page 1769). To specify that the column acts like a combo box, set the column's *ButtonStyle property to cbsAuto. Once you populate the list with values, the grid automatically displays a combo box-like drop-down button when a cell of that column is in edit mode.*

There are two ways to populate that list with the values for users to select:

- You can fetch the values from a lookup table. To make a column display a drop-down list of values drawn from a separate lookup table, you must define a lookup field (see page 1868) in the dataset. Once the lookup field is defined, set the column's *FieldName to the lookup field name. The drop-down list is automatically populated with lookup values defined by the lookup field.*
- You can specify a list of values explicitly at design time. To enter the list values at design time, double-click the *PickList property for the column in the **Object Inspector**. This brings up the String List editor, where you can enter the values that populate the pick list for the column.*

By default, the drop-down list displays 7 values. You can change the length of this list by setting the DropDownRows property.

Note: To restore a column with an explicit pick list to its normal behavior, delete all the text from the pick list using the String List editor.

Setting Column Properties at Design Time (see page 1763)

Restoring Default Values to a Column (see page 1762)

3.2.3.9.4.8 Deleting Persistent Columns

Deleting a persistent column from a grid is useful for eliminating fields that you do not want to display.

To remove a persistent column from a grid

1. Double-click the grid to display the Columns editor.
2. Select the field to remove in the Columns list box.
3. Click Delete (you can also use the context menu or `Del` key, to remove a column).

   Note: If you delete all the columns from a grid, the *Columns.State* property reverts to its *csDefault* state and automatically build dynamic columns for each field in the dataset.

You can delete a persistent column at runtime by simply freeing the column object:

```
DBGrid1.Columns[5].Free;
delete DBGrid1->Columns->Items[5];
```

3.2.3.9.4.9 Displaying ADT and Array Fields

Sometimes the fields of the grid's dataset do not represent simple values such as text, graphics, numerical values, and so on. Some database servers allow fields that are a composite of simpler data types, such as ADT fields or array fields.

There are two ways a grid can display composite fields:

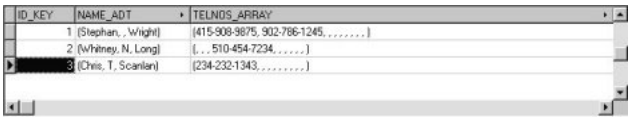
- It can "flatten out" the field so that each of the simpler types that make up the field appears as a separate field in the dataset.
- It can display composite fields in a single column, reflecting the fact that they are a single field.

When a composite field is flattened out, its constituents appear as separate fields that reflect their common source only in that each field name is preceded by the name of the common parent field in the underlying database table.

To display composite fields as if they were flattened out, set the dataset's ObjectView property to *False*. The dataset stores composite fields as a set of separate fields, and the grid reflects this by assigning each constituent part a separate column.

When displaying composite fields in a single column, the column can be expanded and collapsed by clicking on the arrow in the title bar of the field, or by setting the *Expa*nded property of the column:

- When a column is expanded, each child field appears in its own sub-column with a title bar that appears below the title bar of the parent field. That is, the title bar for the grid increases in height, with the first row giving the name of the composite field, and the second row subdividing that for the individual parts. Fields that are not composites appear with title bars that are extra high. This expansion continues for constituents that are in turn composite fields (for example, a detail table nested in a detail table), with the title bar growing in height accordingly.
- When the field is collapsed, only one column appears with an uneditable comma delimited string containing the child fields.



To display a composite field in an expanding and collapsing column, set the dataset's *ObjectView* property to *True*. The dataset stores the composite field as a single field component that contains a set of nested sub-fields. The grid reflects this in a column that can expand or collapse

The following figure shows a grid with an ADT field and an array field. The dataset's *ObjectView* property is set to *False* so that each child field has a column.

TDBGrid control with *ObjectView* set to *False*

The following figures show the grid with an ADT field and an array field. The first figure shows the fields collapsed. In this state they cannot be edited. The second figure shows the fields expanded. The fields are expanded and collapsed by clicking on the arrow in the fields title bar.

TDBGrid control with *Expanded* set to *False*

TDBGrid control with *Expanded* set to *True*

The following table lists the properties that affect the way ADT and array fields appear in a *TDBGrid*:

Properties that affect the way composite fields appear

Property	Object	Purpose
Expandable	TColumn	Indicates whether the column can be expanded to show child fields in separate, editable columns. (read-only)
Expanded	TColumn	Specifies whether the column is expanded.
MaxTitleRows	TDBGrid	Specifies the maximum number of title rows that can appear in the grid
ObjectView	TDataSet	Specifies whether fields are displayed flattened out, or in object mode, where each object field can be expanded and collapsed.
ParentColumn	TColumn	Refers to the TColumn object that owns the child field's column.

Note: In addition to ADT and array fields, some datasets include fields that refer to another dataset (dataset fields) or a record in another dataset (reference) fields. Data-aware grids display such fields as "(DataSet)" or "(Reference)", respectively. At runtime an ellipsis button appears to the right. Clicking on the ellipsis brings up a new form with a grid displaying the contents of the field. For dataset fields, this grid displays the dataset that is the field's value. For reference fields, this grid contains a single row that displays the record from another dataset.

3.2.3.9.4.10 Displaying Fly-over Help

To display fly-over help for each navigator button at runtime, set the navigator ShowHint property to True. When *ShowHint* is True, the navigator displays fly-by Help hints whenever you pass the mouse cursor over the navigator buttons. *ShowHint* is *False* by default.

The Hints property controls the fly-over help text for each button. By default *Hints* is an empty string list. When *Hints* is empty, each navigator button displays default help text. To provide customized fly-over help for the navigator buttons, use the String list

editor to enter a separate line of hint text for each button in the *Hints* property. When present, the strings you provide override the default hints provided by the navigator control.

Using a Single Navigator for Multiple Datasets (see page 1766)

3.2.3.9.4.11 Displaying Multiple Records

Sometimes you want to display many records in the same form. For example, an invoicing application might show all the orders made by a single customer on the same form.

To display multiple records, use a grid control. Grid controls provide a multi-field, multi-record view of data that can make your application's user interface more compelling and effective. They are discussed in Viewing and editing data with TDBGrid (see page 1766) and Creating a grid that contains other data-aware controls (see page 1755).

Note: You can't display multiple records when using a unidirectional dataset.

You may want to design a user interface that displays both fields from a single record and grids that represent multiple records. There are two models that combine these two approaches:

- **Master-detail forms**: You can represent information from both a master table and a detail table by including both controls that display a single field and grid controls. For example, you could display information about a single customer with a detail grid that displays the orders for that customer. For information about linking the underlying tables in a master-detail form, see Creating Master/detail Relationships (see page 1590) and Establishing master/detail relationships using parameters (see page 1593).
- **Drill-down forms**: In a form that displays multiple records, you can include single field controls that display detailed information from the current record only. This approach is particularly useful when the records include long memos or graphic information. As the user scrolls through the records of the grid, the memo or graphic updates to represent the value of the current record. Setting this up is very easy. The synchronization between the two displays is automatic if the grid and the memo or image control share a common data source.

  Tip: It is generally not a good idea to combine these two approaches on a single form. It is usually confusing for users to understand the data relationships in such forms.

Displaying a Single Record

Analyzing Data (see page 1567)

Writing Reports (see page 1568)

3.2.3.9.4.12 Editing in the Grid

At runtime, you can use a grid to modify existing data and enter new records, if the following default conditions are met:

- The CanModify property of the *Dataset* is *True*.
- The ReadOnly property of grid is *False*.

When a user edits a record in the grid, changes to each field are posted to an internal record buffer, but are not posted until the user moves to a different record in the grid. Even if focus is changed to another control on a form, the grid does not post changes until another the cursor for the dataset is moved to another record. When a record is posted, the dataset checks all associated data-aware components for a change in status. If there is a problem updating any fields that contain modified data, the grid raises an exception, and does not modify the record.

Note: If your application caches updates, posting record changes only adds them to an internal cache. They are not posted back to the underlying database table until your application applies the updates.

You can cancel all edits for a record by pressing Esc in any field before moving to another record.

3.2.3.9.4.13 Putting a Button in a Column

A column can display an ellipsis button (...) to the right of the normal cell editor. `Ctrl+Enter` or a mouse click fires the grid's OnEditButtonClick event. You can use the ellipsis button to bring up forms containing more detailed views of the data in the column. For example, in a table that displays summaries of invoices, you could set up an ellipsis button in the invoice total column to bring up a form that displays the items in that invoice, or the tax calculation method, and so on. For graphic fields, you could use the ellipsis button to bring up a form that displays an image.

To create an ellipsis button in a column

1. Select the column in the *Columns* list box.
2. Set *ButtonStyle* to *cbsEllipsis*.
3. Write an *OnEditButtonClick* event handler.

Setting Column Properties at Design Time (see page 1763)

Restoring Default Values to a Column (see page 1762)

3.2.3.9.4.14 Responding to User Actions at Runtime

You can modify grid behavior by writing event handlers to respond to specific actions within the grid at runtime. Because a grid typically displays many fields and records at once, you may have very specific needs to respond to changes to individual columns. For example, you might want to activate and deactivate a button elsewhere on the form every time a user enters and exits a specific column.

The following table lists the grid events available in the **Object Inspector**.

Grid control events

Event	Purpose
OnCellClick	Occurs when a user clicks on a cell in the grid.
OnColEnter	Occurs when a user moves into a column on the grid.
OnColExit	Occurs when a user leaves a column on the grid.
OnColumnMoved	Occurs when the user moves a column to a new location.

OnDblClick	Occurs when a user double clicks in the grid.
OnDragDrop	Occurs when a user drags and drops in the grid.
OnDragOver	Occurs when a user drags over the grid.
OnDrawColumnCell	Occurs when application needs to draw individual cells.
OnDrawDataCell	(obsolete) Occurs when application needs to draw individual cells if *State* is *csDefault*.
OnEditButtonClick	Occurs when the user clicks on an ellipsis button in a column.
OnEndDrag	Occurs when a user stops dragging on the grid.
OnEnter	Occurs when the grid gets focus.
OnExit	Occurs when the grid loses focus.
OnKeyDown	Occurs when a user presses any key or key combination on the keyboard when in the grid.
OnKeyPress	Occurs when a user presses a single alphanumeric key on the keyboard when in the grid.
OnKeyUp	Occurs when a user releases a key when in the grid.
OnStartDrag	Occurs when a user starts dragging on the grid.
OnTitleClick	Occurs when a user clicks the title for a column.

There are many uses for these events. For example, you might write a handler for the OnDblClick event that pops up a list from which a user can choose a value to enter in a column. Such a handler would use the SelectedField property to determine to current row and column.

3.2.3.9.4.15 Restoring Default Values to a Column

At runtime you can test a column's AssignedValues property to determine whether a column property has been explicitly assigned. Values that are not explicitly defined are dynamically based on the associated field or the grid's defaults.

You can undo property changes made to one or more columns. In the Columns editor, select the column or columns to restore, and then select Restore Defaults from the context menu. Restore defaults discards assigned property settings and restores a column's properties to those derived from its underlying field component

At runtime, you can reset all default properties for a single column by calling the column's RestoreDefaults method. You can also reset default properties for all columns in a grid by calling the column list's *RestoreDefaults* method:

```
DBGrid1.Columns.RestoreDefaults;
DBGrid1->Columns->RestoreDefaults();
```

Setting Column Properties at Design Time (see page 1763)

3.2.3.9.4.16 Setting Column Properties at Design Time

Column properties determine how data is displayed in the cells of that column. Most column properties obtain their default values from properties associated with another component (called the *default source*) such as a grid or an associated field component.

To set a column's properties, select the column in The Columns editor and set its properties in the **Object Inspector**. The following table summarizes key column properties you can set.

Column properties

Property	Purpose
Alignment	Left justifies, right justifies, or centers the field data in the column. Default source: *TField*.*Alignment*.
ButtonStyle	*cbsAuto*: (default) Displays a drop-down list if the associated field is a lookup field, or if the column's *PickList* property contains data. *cbsEllipsis*: Displays an ellipsis (...) button to the right of the cell. Clicking on the button fires the grid's *OnEditButtonClick* event. *cbsNone*: The column uses only the normal edit control to edit data in the column.
Color	Specifies the background color of the cells of the column. Default source: *TDBGrid*.*Color*. (For text foreground color, see the Font property.)
DropDownRows	The number of lines of text displayed by the drop-down list. Default: 7.
Expanded	Specifies whether the column is expanded. Only applies to columns representing ADT or array fields.
FieldName	Specifies the field name associated with this column. This can be blank.
ReadOnly	*True*: The data in the column cannot be edited by the user. *False*: (default) The data in the column can be edited.
Width	Specifies the width of the column in screen pixels. Default source: *TField*.*DisplayWidth*.
Font	Specifies the font type, size, and color used to draw text in the column. Default source: *TDBGrid*.*Font*.
PickList	Contains a list of values to display in a drop-down list in the column.
Title	Sets properties for the title of the selected column.

The following table summarizes the options you can specify for the Title property.

Expanded TColumn Title properties

Property	Purpose
Alignment	Left justifies (default), right justifies, or centers the caption text in the column title.
Caption	Specifies the text to display in the column title. Default source: *TField*.*DisplayLabel*.
Color	Specifies the background color used to draw the column title cell. Default source: *TDBGrid*.*FixedColor*.
Font	Specifies the font type, size, and color used to draw text in the column title. Default source: *TDBGrid*.*TitleFont*.

3.2.3.9.4.17 Setting Grid Options

You can use the grid Options property at design time to control basic grid behavior and appearance at runtime. When a grid component is first placed on a form at design time, the *Options* property in the **Object Inspector** is displayed with a + (plus) sign to indicate that the *Options* property can be expanded to display a series of Boolean properties that you can set individually. To view and set these properties, click on the + sign. The list of options in the **Object Inspector** below the *Options* property. The + sign changes to a –(minus) sign, that collapses the list back when you click it.

The following table lists the *Options* properties that can be set, and describes how they affect the grid at runtime.

Expanded TDBGrid Options properties

Option	Purpose
dgEditing	*True*: (Default). Enables editing, inserting, and deleting records in the grid. False: Disables editing, inserting, and deleting records in the grid.
dgAlwaysShowEditor	*True*: When a field is selected, it is in Edit state. False: (Default). A field is not automatically in Edit state when selected.
dgTitles	*True*: (Default). Displays field names across the top of the grid. False: Field name display is turned off.
dgIndicator	*True*: (Default). The indicator column is displayed at the left of the grid, and the current record indicator (an arrow at the left of the grid) is activated to show the current record. On insert, the arrow becomes an asterisk. On edit, the arrow becomes an I-beam. False: The indicator column is turned off.
dgColumnResize	*True*: (Default). Columns can be resized by dragging the column rulers in the title area. Resizing changes the corresponding width of the underlying *TField* component. False: Columns cannot be resized in the grid.
dgColLines	*True*: (Default). Displays vertical dividing lines between columns. False: Does not display dividing lines between columns.
dgRowLines	*True*: (Default). Displays horizontal dividing lines between records. False: Does not display dividing lines between records.
dgTabs	*True*: (Default). Enables tabbing between fields in records. False: Tabbing exits the grid control.
dgRowSelect	*True*: The selection bar spans the entire width of the grid. False: (Default). Selecting a field in a record selects only that field.
dgAlwaysShowSelection	*True*: (Default). The selection bar in the grid is always visible, even if another control has focus. False: The selection bar in the grid is only visible when the grid has focus.
dgConfirmDelete	*True*: (Default). Prompt for confirmation to delete records (`Ctrl+Del`). False: Delete records without confirmation.
dgCancelOnExit	*True*: (Default). Cancels a pending insert when focus leaves the grid. This option prevents inadvertent posting of partial or blank records. False: Permits pending inserts.

dgMultiSelect	*True*: Allows user to select noncontiguous rows in the grid using `Ctrl+Shift` or `Shift+ arrow keys`. False: (Default). Does not allow user to multi-select rows.

3.2.3.9.4.18 Using a Grid Control in Its Default State

The *Stateproperty of the grid's Columns property indicates whether persistent column objects exist for the grid. Columns.State is a runtime-only property that is automatically set for a grid. The default state is csDefault, meaning that persistent column objects do not exist for the grid. In that case, the display of data in the grid is determined primarily by the properties of the fields in the grid's dataset, or, if there are no persistent field components, by a default set of display characteristics.*

When the grid's Columns.State property is csDefault, grid columns are dynamically generated from the visible fields of the dataset and the order of columns in the grid matches the order of fields in the dataset. Every column in the grid is associated with a field component. Property changes to field components immediately show up in the grid.

Using a grid control with dynamically-generated columns is useful for viewing and editing the contents of arbitrary tables selected at runtime. Because the grid's structure is not set, it can change dynamically to accommodate different datasets. A single grid with dynamically-generated columns can display a Paradox table at one moment, then switch to display the results of an SQL query when the grid's DataSource property changes or when the DataSet property of the data source itself is changed.

You can change the appearance of a dynamic column at design time or runtime, but what you are actually modifying are the corresponding properties of the field component displayed in the column. Properties of dynamic columns exist only so long as a column is associated with a particular field in a single dataset. For example, changing the Width property of a column changes the DisplayWidth property of the field associated with that column. Changes made to column properties that are not based on field properties, such as Font, exist only for the lifetime of the column.

If a grid's dataset consists of dynamic field components, the fields are destroyed each time the dataset is closed. When the field components are destroyed, all dynamic columns associated with them are destroyed as well. If a grid's dataset consists of persistent field components, the field components exist even when the dataset is closed, so the columns associated with those fields also retain their properties when the dataset is closed.

Note: *Changing a grid's Columns.State property to csDefault at runtime deletes all column objects in the grid (even persistent columns), and rebuilds dynamic columns based on the visible fields of the grid's dataset.*

Displaying ADT and Array Fields (see page 1758)

3.2.3.9.4.19 Using a Single Navigator for Multiple Datasets

As with other data-aware controls, a navigator's *DataSource property specifies the data source that links the control to a dataset. By changing a navigator's DataSource property at runtime, a single navigator can provide record navigation and manipulation for multiple datasets.*

Suppose a form contains two edit controls linked to the CustomersTable and OrdersTable datasets through the CustomersSource and OrdersSource data sources respectively. When a user enters the edit control connected to CustomersSource, the navigator should also use CustomersSource, and when the user enters the edit control connected to OrdersSource, the navigator should switch to OrdersSource as well. You can code an OnEnter event handler for one of the edit controls, and then share that event with the other edit control. For example:

```
procedure TForm1.CustomerCompanyEnter(Sender :TObject);
begin
  if Sender = CustomerCompany then
    DBNavigatorAll.DataSource := CustomerCompany.DataSource
  else
    DBNavigatorAll.DataSource := OrderNum.DataSource;
end;
void __fastcall TForm1::CustomerCompanyEnter(TObject *Sender)
{
  if (Sender == (TObject *)CustomerCompany)
    DBNavigatorAll->DataSource = CustomerCompany->DataSource;
  else
    DBNavigatorAll->DataSource = OrderNum->DataSource;
}
```

Choosing Navigator Buttons to Display (see page 1752)

Displaying Fly-over Help (see page 1759)

3.2.3.9.4.20 Viewing and Editing Data with TDBGrid

A TDBGrid control lets you view and edit records in a dataset in a tabular grid format.

Three factors affect the appearance of records displayed in a grid control:

- Existence of persistent column objects defined for the grid using the Columns editor. Persistent column objects provide great flexibility setting grid and data appearance. For information on using persistent columns, see Creating a customized grid (see page 1754).
- Creation of persistent field components for the dataset displayed in the grid. For more information about creating persistent field components using the Fields editor, see Working with field components (see page 1877).
- The dataset's *ObjectView* property setting for grids displaying ADT and array fields. See Displaying ADT and array fields (see page 1758).

A grid control has a *Columns property that is itself a wrapper on a TDBGridColumns object. TDBGridColumns is a collection of TColumn objects representing all of the columns in a grid control. You can use the Columns editor to set up column attributes at design time, or use the Columns property of the grid to access the properties, events, and methods of TDBGridColumns at runtime.*

The following topics describe how to use the TDBGrid component:

- Using a Grid Control in Its Default State (see page 1765)
- Creating a Customized Grid (see page 1754)
- Displaying ADT and Array Fields (see page 1758)
- Setting Grid Options (see page 1764)

- Editing in the Grid (see page 1760)
- Controlling Grid Drawing (see page 1753)
- Responding to User Actions at Runtime (see page 1761)

See Also

Creating a Grid That Contains Other Data-aware Controls (see page 1755)

3.2.3.9.4.21 Navigating and Manipulating Records

TDBNavigator provides users a simple control for navigating through records in a dataset, and for manipulating records. The navigator consists of a series of buttons that enable a user to scroll forward or backward through records one at a time, go to the first record, go to the last record, insert a new record, update an existing record, post data changes, cancel data changes, delete a record, and refresh record display.

The following figure shows the navigator that appears by default when you place it on a form at design time. The navigator consists of a series of buttons that let a user navigate from one record to another in a dataset, and edit, delete, insert, and post records. The *VisibleButtons* property of the navigator enables you to hide or show a subset of these buttons dynamically. See Choosing Navigator Buttons to Display (see page 1752) for more information.

The following table describes the buttons on the navigator.

TDBNavigator buttons

Button	Purpose
First	Calls the dataset's *First* method to set the current record to the first record.
Prior	Calls the dataset's *Prior* method to set the current record to the previous record.
Next	Calls the dataset's *Next* method to set the current record to the next record.
Last	Calls the dataset's *Last* method to set the current record to the last record.
Insert	Calls the dataset's *Insert* method to insert a new record before the current record, and set the dataset in Insert state.
Delete	Deletes the current record. If the *ConfirmDelete* property is *True* it prompts for confirmation before deleting.
Edit	Puts the dataset in Edit state so that the current record can be modified.
Post	Writes changes in the current record to the database.
Cancel	Cancels edits to the current record, and returns the dataset to Browse state.
Refresh	Clears data control display buffers, then refreshes its buffers from the physical table or query. Useful if the underlying data may have been changed by another application.

See Displaying fly-over Help (see page 1759) for information on associating help hints with each button. See Using a Single Navigator for Multiple Datasets (see page 1766) for information about associating a navigator with multiple datasets.

3.2.3.9.5 Disabling and Enabling Data Display

When your application iterates through a dataset or performs a search, you should temporarily prevent refreshing of the values displayed in data-aware controls each time the current record changes. Preventing refreshing of values speeds the iteration or search and prevents annoying screen-flicker.

DisableControls is a dataset method that disables display for all data-aware controls linked to a dataset. As soon as the iteration or search is over, your application should immediately call the dataset's EnableControls method to re-enable display for the controls.

Usually you disable controls before entering an iterative process. The iterative process itself should take place inside a ***try...finally*** *statement so that you can re-enable controls even if an exception occurs during processing. The* ***finally*** *clause should call EnableControls. The following code illustrates how you might use DisableControls and EnableControls in this manner:*

```
CustTable.DisableControls;
try
CustTable.First; { Go to first record, which sets EOF False }
while not CustTable.EOF do { Cycle until EOF is True }
begin
{ Process each record here }
    .
    .
    .
CustTable.Next; { EOF False on success; EOF True when Next fails on last record }
end;
finally
CustTable.EnableControls;
end;
```

```
CustTable->DisableControls();
try
{
  // cycle through all records of the dataset
  for (CustTable->First(); !CustTable->EOF; CustTable->Next())
  {
  // Process each record here
  .
  .
  .
  }
}
__finally
{
  CustTable->EnableControls();
}
```

3.2.3.9.6 Displaying and Editing Data in List and Combo Boxes

There are four data controls that provide the user with a set of default data values to choose from at runtime. These are

data-aware versions of standard list and combo box controls:

- TDBListBox, which displays a scrollable list of items from which a user can choose to enter in a data field. A data-aware list box displays a default value for a field in the current record and highlights its corresponding entry in the list. If the current row's field value is not in the list, no value is highlighted in the list box. When a user selects a list item, the corresponding field value is changed in the underlying dataset.
- TDBComboBox, which combines the functionality of a data-aware edit control and a drop-down list. At runtime it can display a drop-down list from which a user can pick from a predefined set of values, and it can permit a user to enter an entirely different value.
- TDBLookupListBox, which behaves like *TDBListBox* except the list of display items is looked up in another dataset.
- TDBLookupComboBox, which behaves like *TDBComboBox* except the list of display items is looked up in another dataset.

The following topics describe these components in more detail:

- Using TDBListBox and TDBComboBox (see page 1778)
- Displaying and Editing Data in Lookup List and Combo Boxes (see page 1769)

Note: At runtime, users can use an incremental search to find list box items. When the control has focus, for example, typing 'ROB' selects the first item in the list box beginning with the letters 'ROB'. Typing an additional 'E' selects the first item starting with 'ROBE', such as 'Robert Johnson'. The search is case-insensitive. Backspace

and Esc cancel the current search string (but leave the selection intact), as does a two second pause between keystrokes.

3.2.3.9.7 Displaying and Editing Data in Lookup List and Combo Boxes

Lookup list boxes and lookup combo boxes (TDBLookupListBox and TDBLookupComboBox) present the user with a restricted list of choices from which to set a valid field value. When a user selects a list item, the corresponding field value is changed in the underlying dataset.

For example, consider an order form whose fields are tied to the *OrdersTable*. *OrdersTable* contains a *CustNo* field corresponding to a customer ID, but *OrdersTable* does not have any other customer information. The *CustomersTable*, on the other hand, contains a *CustNo* field corresponding to a customer ID, and also contains additional information, such as the customer's company and mailing address. It would be convenient if the order form enabled a clerk to select a customer by company name instead of customer ID when creating an invoice. A *TDBLookupListBox* that displays all company names in *CustomersTable* enables a user to select the company name from the list, and set the *CustNo* on the order form appropriately.

These lookup controls derive the list of display items from one of two sources:

A lookup field defined for a dataset. To specify list box items using a lookup field, the dataset to which you link the control must already define a lookup field (see page 1868).

To specify the lookup field for the list box items

1. Set the DataSource property of the list box to the data source for the dataset containing the lookup field to use.

2. Choose the lookup field to use from the drop-down list for the DataField property.
3. When you activate a table associated with a lookup control, the control recognizes that its data field is a lookup field, and displays the appropriate values from the lookup.

A secondary data source, data field, and key. If you have not defined a lookup field for a dataset, you can establish a similar relationship using a secondary data source, a field value to search on in the secondary data source, and a field value to return as a list item.

To specify a secondary data source for list box items

1. Set the DataSource property of the list box to the data source for the control.
2. Choose a field into which to insert looked-up values from the drop-down list for the DataField*property. The field you choose cannot be a lookup field.*
3. Set the ListSource property of the list box to the data source for the dataset that contain the field whose values you want to look up.
4. Choose a field to use as a lookup key from the drop-down list for the KeyField property. The drop-down list displays fields for the dataset associated with data source you specified in Step 3. The field you choose need not be part of an index, but if it is, lookup performance is even faster.
5. Choose a field whose values to return from the drop-down list for the ListField property. The drop-down list displays fields for the dataset associated with the data source you specified in Step 3.

When you activate a table associated with a lookup control, the control recognizes that its list items are derived from a secondary source, and displays the appropriate values from that source.

To specify the number of items that appear at one time in a *TDBLookupListBox* control, use the RowCount property. The height of the list box is adjusted to fit this row count exactly.

To specify the number of items that appear in the drop-down list of *TDBLookupComboBox*, use the DropDownRows property instead.

Note: You can also set up a column in a data grid to act as a lookup combo box. For information on how to do this, see Defining a lookup list column (see page 1757).

Using TDBListBox and TDBComboBox (see page 1778)

3.2.3.9.8 Displaying and Editing Fields in an Edit Box

TDBEdit is a data-aware version of an edit box component. *TDBEdit* displays the current value of a data field to which it is linked and permits it to be edited using standard edit box techniques.

For example, suppose *CustomersSource* is a *TDataSource* component that is active and linked to an open TClientDataSet called *CustomersTable*. You can then place a *TDBEdit* component on a form and set its properties as follows:

- *DataSource*: CustomersSource
- *DataField*: CustNo

The data-aware edit box component immediately displays the value of the current row of the *CustNo* column of the *CustomersTable* dataset, both at design time and at runtime.

Handling Boolean Field Values with Check Boxes (see page 1775)

Restricting Field Values with Radio Controls (see page 1748)

3.2.3.9.9 Displaying and Editing Graphics Fields in an Image Control

TDBImage is a data-aware control that displays graphics contained in BLOB fields.

By default, *TDBImage* permits a user to edit a graphics image by cutting and pasting to and from the Clipboard using the CutToClipboard, CopyToClipboard, and PasteFromClipboard methods. You can, instead, supply your own editing methods attached to the event handlers for the control.

By default, an image control displays as much of a graphic as fits in the control, cropping the image if it is too big. You can set the *Stretch property to True to resize the graphic to fit within an image control as it is resized.*

Because the TDBImage can display large amounts of data, it can take time to populate the display at runtime. To reduce the time it takes scroll through data records, TDBImage has an AutoDisplay property that controls whether the accessed data should automatically displayed. If you set AutoDisplay to False, TDBImage displays the field name rather than actual data. Double-click inside the control to view the actual data.

Restricting Field Values with Radio Controls (see page 1748)

3.2.3.9.10 Displaying and Editing Text in a Memo Control

TDBMemo is a data-aware component—similar to the standard TMemo component—that can display lengthy text data. *TDBMemo* displays multi-line text, and permits a user to enter multi-line text as well. You can use *TDBMemo* controls to display large text fields or text data contained in binary large object (BLOB) fields.

By default, *TDBMemo* permits a user to edit memo text. To prevent editing, set the *ReadOnly property of the memo control to True. To display tabs and permit users to enter them in a memo, set the WantTabs property to True. To limit the number of characters users can enter into the database memo, use the MaxLength property. The default value for MaxLength is 0, meaning that there is no character limit other than that imposed by the operating system.*

Several properties affect how the database memo appears and how text is entered. You can supply scroll bars in the memo with the ScrollBars property. To prevent word wrap, set the WordWrap property to False. The Alignment property determines how the text is aligned within the control. Possible choices are taLeftJustify (the default), taCenter, and taRightJustify. To change the font of the text, use the Font property.

At runtime, users can cut, copy, and paste text to and from a database memo control. You can accomplish the same task programmatically by using the CutToClipboard, CopyToClipboard, and PasteFromClipboard methods.

Because the TDBMemo can display large amounts of data, it can take time to populate the display at runtime. To reduce the time it takes to scroll through data records, TDBMemo has an AutoDisplay property that controls whether the accessed data should be displayed automatically. If you set AutoDisplay to False, TDBMemo displays the field name rather than actual data. Double-click inside the control to view the actual data.

3.2.3.9.11 Displaying and Editing Text in a Rich Edit Memo Control

TDBRichEdit is a data-aware component—similar to the standard *TRichEdit* component—that can display formatted text stored in a binary large object (BLOB) field. *TDBRichEdit* displays formatted, multi-line text, and permits a user to enter formatted multi-line text as well.

Note: While *TDBRichEdit* provides properties and methods to enter and work with rich text, it does not provide any user interface components to make these formatting options available to the user. Your application must implement the user interface to surface rich text capabilities.

By default, *TDBRichEdit* permits a user to edit memo text. To prevent editing, set the *ReadOnly property of the rich edit control to True. To display tabs and permit users to enter them in a memo, set the WantTabs property to True. To limit the number of characters users can enter into the database memo, use the MaxLength property. The default value for MaxLength is 0, meaning that there is no character limit other than that imposed by the operating system.*

Because the TDBRichEdit can display large amounts of data, it can take time to populate the display at runtime. To reduce the time it takes to scroll through data records, TDBRichEdit has an AutoDisplay property that controls whether the accessed data should be displayed automatically. If you set AutoDisplay to False, TDBRichEdit displays the field name rather than actual data. Double-click inside the control to view the actual data.

3.2.3.9.12 Displaying Data as Labels

TDBText is a read-only control similar to the TLabel component on the Standard category of the **Tool palette**. A *TDBText* control is useful when you want to provide display-only data on a form that allows user input in other controls. For example, suppose a form is created around the fields in a customer list table, and that once the user enters a street address, city, and state or province information in the form, you use a dynamic lookup to automatically determine the zip code field from a separate table. A *TDBText* component tied to the zip code table could be used to display the zip code field that matches the address entered by

the user.

TDBText gets the text it displays from a specified field in the current record of a dataset. Because *TDBText* gets its text from a dataset, the text it displays is dynamic—the text changes as the user navigates the database table. Therefore you cannot specify the display text of *TDBText* at design time as you can with *TLabel*.

Note: When you place a *TDBText* component on a form, make sure its AutoSize property is *True* (the default) to ensure that the control resizes itself as necessary to display data of varying widths. If *AutoSize* is *False*, and the control is too small, data display is clipped.

3.2.3.9.13 Editing and Updating Data

All data controls except the navigator display data from a database field. In addition, you can use them to edit and update data as long as the underlying dataset allows it.

Note: Unidirectional datasets never permit users to edit and update data.

The following topics describe how to allow users to edit data using data controls:

- Enabling Editing in Controls On User Entry (see page 1774)
- Editing Data in a Control (see page 1773)

See Also

Associating a Data Control with a Dataset (see page 1746)

Disabling and Enabling Data Display (see page 1768)

Refreshing Data Display (see page 1776)

Enabling Mouse (see page 1774)

3.2.3.9.14 Editing Data in a Control

A data control can only post edits to its associated dataset if the dataset's CanModify property is *True*. *CanModify* is always *False* for unidirectional datasets. Some datasets have a *ReadOnly* property that lets you specify whether *CanModify* is *True*.

Note: Whether a dataset can update data depends on whether the underlying database table permits updates.

Even if the dataset's *CanModify* property is *True*, the Enabled property of the data source that connects the dataset to the control must be *True* as well before the control can post updates back to the database table. The *Enabled* property of the data source determines whether the control can display field values from the dataset, and therefore also whether a user can edit and post values. If *Enabled* is *True* (the default), controls can display field values.

Finally, you can control whether the user can even enter edits to the data that is displayed in the control. The *ReadOnly* property

of the data control determines if a user can edit the data displayed by the control. If *False* (the default), users can edit data. Clearly, you will want to ensure that the control's *ReadOnly* property is *True* when the dataset's *CanModify* property is *False*. Otherwise, you give users the false impression that they can affect the data in the underlying database table.

In all data controls except TDBGrid, when you modify a field, the modification is copied to the underlying dataset when you `Tab` from the control. If you press `Esc` before you `Tab` from a field, the data control abandons the modifications, and the value of the field reverts to the value it held before any modifications were made.

In TDBGrid, modifications are posted when you move to a different record; you can press `Esc` in any record of a field before moving to another record to cancel all changes to the record.

When a record is posted, Delphi checks all data-aware controls associated with the dataset for a change in status. If there is a problem updating any fields that contain modified data, Delphi raises an exception, and no modifications are made to the record.

Note: If your application caches updates (for example, using a client dataset), all modifications are posted to an internal cache. These modifications are not applied to the underlying database table until you call the dataset's *ApplyUpdates* method.

See Also

Enabling Editing in Controls On User Entry (see page 1774)

3.2.3.9.15 Enabling and Disabling the Data Source

The data source has an Enabled property that determines if it is connected to its dataset. When *Enabled* is *True*, the data source is connected to a dataset.

You can temporarily disconnect a single data source from its dataset by setting *Enabled* to *False*. When *Enabled* is *False*, all data controls attached to the data source component go blank and become inactive until *Enabled* is set to *True*. It is recommended, however, to control access to a dataset through a dataset component's DisableControls and EnableControls methods because they affect all attached data sources.

See Also

Changing the Associated Dataset at Runtime (see page 1747)

Responding to Changes Mediated by the Data Source (see page 1776)

3.2.3.9.16 Enabling Editing in Controls On User Entry

A dataset must be in *dsEdit* state to permit editing to its data. If the data source's AutoEdit property is *True* (the default), the data control handles the task of putting the dataset into *dsEdit* mode as soon as the user tries to edit its data.

If *AutoEdit* is *False*, you must provide an alternate mechanism for putting the dataset into edit mode. One such mechanism is to use a TDBNavigator control with an *Edit* button, which lets users explicitly put the dataset into edit mode. For more information about *TDBNavigator*, see Navigating and manipulating records (see page 1767). Alternately, you can write code that calls the dataset's Edit method when you want to put the dataset into edit mode.

See Also

Editing Data in a Control (see page 1773)

Enabling and Disabling the Data Source (see page 1774)

3.2.3.9.17 Enabling Mouse, Keyboard, and Timer Events

The Enabled property of a data control determines whether it responds to mouse, keyboard, or timer events, and passes information to its data source. The default setting for this property is *True*.

To prevent mouse, keyboard, or timer events from reaching a data control, set its *Enabled* property to *False*. When *Enabled* is *False*, the data source that connects the control to its dataset does not receive information from the data control. The data control continues to display data, but the text displayed in the control is dimmed.

See Also

Associating a Data Control with a Dataset (see page 1746)

Disabling and Enabling Data Display (see page 1768)

Refreshing Data Display (see page 1776)

Editing and Updating Data (see page 1773)

3.2.3.9.18 Handling Boolean Field Values with Check Boxes

TDBCheckBox is a data-aware check box control. It can be used to set the values of Boolean fields in a dataset. For example, a customer invoice form might have a check box control that when checked indicates the customer is tax-exempt, and when unchecked indicates that the customer is not tax-exempt.

The data-aware check box control manages its checked or unchecked state by comparing the value of the current field to the contents of ValueChecked and ValueUnchecked properties. If the field value matches the *ValueChecked* property, the control is checked. Otherwise, if the field matches the *ValueUnchecked* property, the control is unchecked.

Note: The values in *ValueChecked* and *ValueUnchecked* cannot be identical.

Set the *ValueChecked* property to a value the control should post to the database if the control is checked when the user moves to another record. By default, this value is set to "true," but you can make it any alphanumeric value appropriate to your needs. You can also enter a semicolon-delimited list of items as the value of *ValueChecked*. If any of the items matches the contents of that field in the current record, the check box is checked. For example, you can specify a *ValueChecked* string like:

```
DBCheckBox1.ValueChecked := 'True;Yes;On';
DBCheckBox1->ValueChecked = "true;Yes;On";
```

If the field for the current record contains values of "True," "Yes," or "On," then the check box is checked. Comparison of the field to *ValueChecked* strings is case-insensitive. If a user checks a box for which there are multiple *ValueChecked* strings, the first string is the value that is posted to the database.

Set the *ValueUnchecked* property to a value the control should post to the database if the control is not checked when the user moves to another record. By default, this value is set to "false," but you can make it any alphanumeric value appropriate to your needs. You can also enter a semicolon-delimited list of items as the value of *ValueUnchecked*. If any of the items matches the contents of that field in the current record, the check box is unchecked.

A data-aware check box is disabled whenever the field for the current record does not contain one of the values listed in the *ValueChecked* or *ValueUnchecked* properties.

If the field with which a check box is associated is a logical field, the check box is always checked if the contents of the field is *True*, and it is unchecked if the contents of the field is *False*. In this case, strings entered in the *ValueChecked* and *ValueUnchecked* properties have no effect on logical fields.

Restricting Field Values with Radio Controls (see page 1748)

3.2.3.9.19 Refreshing Data Display

The Refresh method for a dataset flushes local buffers and re-fetches data for an open dataset. You can use this method to update the display in data-aware controls if you think that the underlying data has changed because other applications have simultaneous access to the data used in your application. If you are using cached updates, before you refresh the dataset you must apply any updates the dataset has currently cached.

Refreshing can sometimes lead to unexpected results. For example, if a user is viewing a record deleted by another application, then the record disappears the moment your application calls *Refresh*. Data can also appear to change if another user changes a record after you originally fetched the data and before you call *Refresh*.

See Also

Associating a Data Control with a Dataset (see page 1746)

Disabling and Enabling Data Display (see page 1768)

Editing and Updating Data (see page 1773)

Enabling Mouse (see page 1774)

3.2.3.9.20 Responding to Changes Mediated by the Data Source

Because the data source provides the link between the data control and its dataset, it mediates all of the communication that occurs between the two. Typically, the data-aware control automatically responds to changes in the dataset. However, if your user interface is using controls that are not data-aware, you can use the events of a data source component to manually provide the same sort of response.

The OnDataChange event occurs whenever the data in a record may have changed, including field edits or when the cursor moves to a new record. This event is useful for making sure the control reflects the current field values in the dataset, because it is triggered by all changes. Typically, an *OnDataChange* event handler refreshes the value of a non-data-aware control that displays field data.

The UpdateData event occurs when the data in the current record is about to be posted. For instance, an *OnUpdateData* event occurs after Post is called, but before the data is actually posted to the underlying database server or local cache.

The StateChange event occurs when the state of the dataset changes. When this event occurs, you can examine the dataset's State property to determine its current state.

For example, the following *OnStateChange* event handler enables or disables buttons or menu items based on the current state:

```
procedure Form1.DataSource1.StateChange(Sender: TObject);
begin
  CustTableEditBtn.Enabled := (CustTable.State = dsBrowse);
  CustTableCancelBtn.Enabled := CustTable.State in [dsInsert, dsEdit, dsSetKey];
  CustTableActivateBtn.Enabled := CustTable.State in [dsInactive];
  .
  .
  .
end;
void __fastcall TForm1::DataSource1StateChange(TObject *Sender)
{
  CustTableActivateBtn->Enabled = (CustTable->State == dsInactive);
  CustTableEditBtn->Enabled = (CustTable->State == dsBrowse);
  CustTableCancelBtn->Enabled = (CustTable->State == dsInsert ||
                                 CustTable->State == dsEdit ||
```

```
                                    CustTable->State == dsSetKey);
    .
    .
    .
}
```

Note: For more information about dataset states, see Determining Dataset States (see page 1633).

Changing the Associated Dataset at Runtime (see page 1747)

Enabling and Disabling the Data Source (see page 1774)

3.2.3.9.21 Using Common Data Control Features

The following tasks are common to most data controls:

- Associating a data control with a dataset (see page 1746)
- Editing and updating data (see page 1773)
- Disabling and enabling data display (see page 1768)
- Refreshing data display (see page 1776)
- Enabling mouse (see page 1774)

Data controls let you display and edit fields of data associated with the current record in a dataset. The following table summarizes the data controls that appear on the Data Controls category of the **Tool palette**.

Data controls

Data control	Description
TDBGrid	Displays information from a data source in a tabular format. Columns in the grid correspond to columns in the underlying table or query's dataset. Rows in the grid correspond to records.
TDBNavigator	Navigates through data records in a dataset. updating records, posting records, deleting records, canceling edits to records, and refreshing data display.
TDBText	Displays data from a field as a label.
TDBEdit	Displays data from a field in an edit box.
TDBMemo	Displays data from a memo or BLOB field in a scrollable, multi-line edit box.
TDBImage	Displays graphics from a data field in a graphics box.
TDBListBox	Displays a list of items from which to update a field in the current data record.
TDBComboBox	Displays a list of items from which to update a field, and also permits direct text entry like a standard data-aware edit box.
TDBCheckBox	Displays a check box that indicates the value of a Boolean field.
TDBRadioGroup	Displays a set of mutually exclusive options for a field.
TDBLookupListBox	Displays a list of items looked up from another dataset based on the value of a field.
TDBLookupComboBox	Displays a list of items looked up from another dataset based on the value of a field, and also permits direct text entry like a standard data-aware edit box.
TDBCtrlGrid	Displays a configurable, repeating set of data-aware controls within a grid.
TDBRichEdit	Displays formatted data from a field in an edit box.

Data controls are data-aware at design time. When you associate the data control with an active dataset (see page 1746) while building an application, you can immediately see live data in the control. You can use the Fields editor to scroll through a dataset at design time to verify that your application displays data correctly without having to compile and run the application. For

more information about the Fields editor, see Creating Persistent Fields (see page 1874).

At runtime, data controls display data and, if your application, the control, and the dataset all permit it, a user can edit data through the control.

Choosing How to Organize the Data (see page 1747)

Navigating and Manipulating Records (see page 1767)

3.2.3.9.22 Using TDBListBox and TDBComboBox

When using *TDBListBox* or *TDBComboBox*, you must use the String List editor at design time to create the list of items to display. To bring up the String List editor, click the ellipsis button for the *Items property in the* ***Object Inspector****. Then type in the items that you want to have appear in the list. At runtime, use the methods of the Items property to manipulate its string list.*

When a TDBListBox or TDBComboBox control is linked to a field through its DataField property, the field value appears selected in the list. If the current value is not in the list, no item appears selected. However, TDBComboBox displays the current value for the field in its edit box, regardless of whether it appears in the Items list.

For TDBListBox, the Height property determines how many items are visible in the list box at one time. The IntegralHeight property controls how the last item can appear. If IntegralHeight is False (the default), the bottom of the list box is determined by the ItemHeight property, and the bottom item may not be completely displayed. If IntegralHeight is True, the visible bottom item in the list box is fully displayed.

For TDBComboBox, the Style property determines user interaction with the control. By default, Style is csDropDown, meaning a user can enter values from the keyboard, or choose an item from the drop-down list. The following properties determine how the Items list is displayed at runtime:

- *Style* determines the display style of the component:
- *csDropDown* (default): Displays a drop-down list with an edit box in which the user can enter text. All items are strings and have the same height.
- *csSimple*: Combines an edit control with a fixed size list of items that is always displayed. When setting *Style* to *csSimple*, be sure to increase the *Height* property so that the list is displayed.
- *csDropDownList*: Displays a drop-down list and edit box, but the user cannot enter or change values that are not in the drop-down list at runtime.
- *csOwnerDrawFixed* and *csOwnerDrawVariable*: Allows the items list to display values other than strings (for example, bitmaps) or to use different fonts for individual items in the list.
- DropDownCount: the maximum number of items displayed in the list. If the number of Items is greater than *DropDownCount*, the user can scroll the list. If the number of Items is less than *DropDownCount*, the list will be just large enough to display all the Items.
- ItemHeight: The height of each item when style is *csOwnerDrawFixed*.
- Sorted: If *True*, then the *Items* list is displayed in alphabetical order.

Displaying and Editing Data in Lookup List and Combo Boxes (see page 1769)

3.2.3.9.23 Using Data Controls

The Data Controls category of the **Tool palette** provides a set of data-aware controls that represent data from fields in a database record, and, if the dataset allows it, enable users to edit that data and post changes back to the database. By placing data controls onto the forms in your database application, you can build your database application's user interface (UI) so that information is visible and accessible to users.

The data-aware controls you add to your user interface depend on several factors, including the following:

- The type of data you are displaying. You can choose between controls that are designed to display and edit plain text, controls that work with formatted text, controls for graphics, multimedia elements, and so on. Controls that display different types of information are described in Displaying a Single Record.
- How you want to organize the information. You may choose to display information from a single record on the screen, or list the information from multiple records using a grid. Choosing how to organize the data describes some of the possibilities.
- The type of dataset that supplies data to the controls. You want to use controls that reflect the limitations of the underlying dataset. For example, you would not use a grid with a unidirectional dataset because unidirectional datasets can only supply a single record at a time.
- How (or if) you want to let users navigate through the records of datasets and add or edit data. You may want to add your own controls or mechanisms to navigate and edit, or you may want to use a built-in control such as a data navigator (see page 1767).

  Note: More complex data-aware controls for decision support are discussed in Using Decision Support Components (see page 1800).

  Regardless of the data-aware controls you choose to add to your interface, certain common features apply. These are described in Using Common Data Control Features (see page 1777).

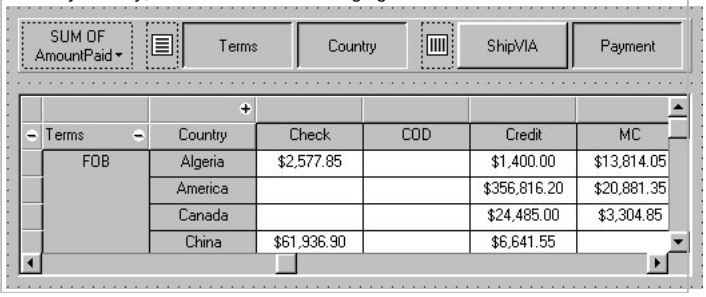
3.2.3.10 Using decision support components



Topics

Name	Description
Changing Other Decision Graph Series Properties (see page 1786)	
Changing Other Decision Graph Template Properties (see page 1786)	
Changing the Default Decision Graph Type (see page 1786)	
Changing the Series Graph Type (see page 1787)	By default, each series has the same graph type, defined by the template for its dimension. To change all series to the same graph type, you can change the template type. See Changing other decision graph series properties. (see page 1786) for instructions.
Creating Decision Datasets with TQuery or TTable (see page 1787)	If you use an ordinary TQuery component as a decision dataset, you must manually set up the SQL statement, taking care to supply a GROUP BY phrase which contains the same fields (and in the same order) as the SELECT phrase. The SQL should look similar to this:

Creating Decision Grids (see page 1788)	
Decision Cube Properties and Events (see page 1788)	The DimensionMap properties of *TDecisionCube* not only control which dimensions and summaries appear but also let you set date ranges and specify the maximum number of dimensions the decision cube may support. You can also indicate whether or not to display data during design. You can display names, (categories) values, subtotals, or data. Display of data at design time can be time consuming, depending on the data source. When you click the ellipsis next to *DimensionMap* in the **Object Inspector**, the Decision Cube editor dialog box appears. You can use its pages and controls to set the *DimensionMap* properties.... more (see page 1788)
Decision Graphs at Runtime (see page 1788)	Users can drag from side to side or up and down in the graph grid area to scroll through off-screen categories and values.
Decision Grids at Runtime (see page 1788)	Users can: Right-click within the decision grid and choose to: • Toggle subtotals on and off for individual data groups, for all values of a dimension, or for the whole grid. • Display the Decision Cube editor, described in Using the Decision Cube editor. (see page 1796) • Toggle dimensions and summaries open and closed. Click + and – within the row and column headings to open and close dimensions. Drag and drop dimensions from rows to columns and the reverse.
Decision Pivots: Runtime Behavior (see page 1789)	Users can: Left-click the summary button at the left end of the decision pivot to display a list of available summaries. They can use this list to change the summary data displayed in decision grids and decision graphs. Right-click a dimension button and choose to: • Move it from the row area to the column area or the reverse. • Drill In to display detail data. Left-click a dimension button following the Drill In command and choose: • Open Dimension to move back to the top level of that dimension. • All Values to toggle between displaying just summaries and summaries plus all other... more (see page 1789)
Decision Support Components at Runtime (see page 1789)	At runtime, users can perform many operations by left-clicking, right-clicking, and dragging visible decision support components. These operations are summarized below. • Decision Pivots at Runtime (see page 1789) • Decision Grids at Runtime (see page 1788) • Decision Graphs at Runtime (see page 1788)
Drilling Down for Detail in Decision Grids (see page 1790)	You can drill down to see more detail in a dimension. For example, if you right-click a category label (row heading) for a dimension with others collapsed beneath it, you can choose to drill down and only see data for that category. When a dimension is drilled, you do not see the category labels for that dimension displayed on the grid, since only the records for a single category value are being displayed. If you have a decision pivot on the form, it displays category values and lets you change to other values if you want. To drill down into... more (see page 1790)
Limiting Dimension Selection in Decision Grids (see page 1790)	You can change the *ControlType* property of the decision source to determine whether more than one dimension can be selected for each axis of the grid. For more information, see Using Decision Sources. (see page 1803)

Opening and Closing Decision Grid Fields (see page 1790)	If a plus sign (+) appears in a dimension or summary field, one or more fields to its right are closed (hidden). You can open additional fields and categories by clicking the sign. A minus sign (–) indicates a fully opened (expanded) field. When you click the sign, the field closes. This outlining feature can be disabled; see Decision Grid Properties (see page 1798) for details.
Overview of Decision Support Components (see page 1790)	The decision support components appear on the Decision Cube category of the **Tool Palette**: • The decision cube, TDecisionCube, is a multidimensional data store. For more information see Using decision cubes. (see page 1797) • The decision source, TDecisionSource, defines the current pivot state of a decision grid or a decision graph. For more information, see Using decision sources. (see page 1803) • The decision query, TDecisionQuery, is a specialized form of TQuery used to define the data in a decision cube. For more information, see Using datasets with decision support components. (see page 1799) • The decision pivot, TDecisionPivot, lets you open or close decision cube dimensions, or fields, by pressing... more (see page 1790)
Decision Pivot Properties (see page 1791)	The following are some special properties that control the appearance and behavior of decision pivots: • The first properties listed for *TDecisionPivot* define its overall behavior and appearance. You might want to set *ButtonAutoSize* to *False* for *TDecisionPivot* to keep buttons from expanding and contracting as you adjust the size of the component. • The *Groups* property of *TDecisionPivot* defines which dimension buttons appear. You can display the row, column, and summary selection button groups in any combination. Note that if you want more flexibility over the placement of these groups, you can place one *TDecisionPivot* on your form which contains only... more (see page 1791)
Reorganizing Rows and Columns in Decision Grids (see page 1792)	You can drag row and column headings to new locations within the same axis or to the other axis. In this way, you can reorganize the grid and see the data from new perspectives as the data groupings change. This pivoting feature can be disabled; see Decision Grid Properties (see page 1798) for details. If you included a decision pivot, you can push and drag its buttons to reorganize the display. See Using decision Pivots (see page 1798) for instructions.
Saving Decision Graph Series Settings (see page 1792)	By default, only settings for templates are saved at design time. Changes made to specific series are only saved if the Save box is checked for that series in the **Chart Editing** dialog box. Saving series can be memory intensive, so if you don't need to save them you can uncheck the Save box.
Setting Decision Graph Template Defaults (see page 1792)	Decision graphs display the values from two dimensions of the decision cube: one dimension is displayed as an axis of the graph, and the other is used to create a set of series. The template for that dimension provides default properties for those series (such as whether the series are bar, line, area, and so on). As users pivot from one state to another, any required series for the dimension are created using the series type and other defaults specified in the template. A separate template is provided for cases where users pivot to a state where only one dimension... more (see page 1792)

Setting Dimension State (see page 1792)	The *ActiveFlag* property controls which dimensions get loaded. You can set this property on the Dimension Settings tab of the Decision Cube editor using the Activity Type control. When this control is set to *Active*, the dimension is loaded unconditionally, and will always take up space. Note that the number of dimensions in this state must always be less than *MaxDimensions*, and the number of summaries set to *Active* must be less than *MaxSummaries*. You should set a dimension or summary to *Active* only when it is critical that it be available at all times. An *Active... more (see page 1792)*
Setting Maximum Dimensions, Summaries, and Cells (see page 1793)	The decision cube's *MaxDimensions* and *MaxSummaries* properties can be used with the *CubeDim.ActiveFlag* property to control how many dimensions and summaries can be loaded at a time. You can set the maximum values on the Cube Capacity page of the Decision Cube editor to place some overall control on how many dimensions or summaries can be brought into memory at the same time. Limiting the number of dimensions or summaries provides a rough limit on the amount of memory used by the decision cube. However, it does not distinguish between dimensions with many values and those with only a few.... more (see page 1793)
Setting the Maximum Available Dimensions and Summaries (see page 1793)	To determine the maximum number of dimensions and summaries available for decision pivots, decision grids, and decision graphs bound to the selected decision cube, display the Decision Cube editor and click the Memory Control tab. Use the edit controls to adjust the current settings, if necessary. These settings help to control the amount of memory required by the decision cube. For more information, see Decision Support Components and Memory Control. (see page 1800)
Using Paged Dimensions (see page 1793)	When Binning is set to Set on the Dimension Settings tab of the Decision cube editor and Start Value is not NULL, the dimension is said to be "paged," or "permanently drilled down." You can access data for just a single value of that dimension at a time, although you can programmatically access a series of values sequentially. Such a dimension may not be pivoted or opened. It is extremely memory intensive to include dimensional data for dimensions that have very large numbers of values. By making such dimensions paged, you can display summary information for one value at a... more (see page 1793)
Viewing and Changing Design Options (see page 1794)	To determine how much information appears at design time, display the Decision Cube editor and click the Memory Control tab. Then, check the setting that indicates which names and data to display. Display of data or field names at design time can cause performance delays in some cases because of the time needed to fetch the data.
Viewing and Changing Dimension Settings (see page 1794)	To view the dimension settings, display the Decision Cube editor and click the Dimension Settings tab. Then, select a dimension or summary in the Available Fields list. Its information appears in the boxes on the right side of the editor: • To change the dimension or summary name that appears in the decision pivot, decision grid, or decision graph, enter a new name in the Display Name edit box. • To determine whether the selected field is a dimension or summary, read the text in the Type edit box. If the dataset is a *TTable* component, you can use Type to specify... more (see page 1794)
Viewing Overall Decision Graph Properties (see page 1794)	
One-Dimensional Crosstabs (see page 1795)	One-dimensional crosstabs show a summary row (or column) for the categories of a single dimension. For example, if Payment is the chosen column dimension and Amount Paid is the summary category, the crosstab in the following figure shows the amount paid using each method. 

Using Decision Graphs (see page 1795)	The decision graph component, TDecisionGraph, displays fields from the decision source TDecisionSource as a dynamic graph that changes when data dimensions are opened, closed, dragged and dropped, or rearranged with the decision pivot TDecisionPivot. Graphed data comes from a specially formatted dataset such as TDecisionQuery. For an overview of how the decision support components handle and arrange this data, see Using Decision Support Components. (see page 1800) By default, the first row dimension appears as the x-axis and the first column dimension appears as the y-axis. You can use decision graphs instead of or in addition to decision grids, which present cross-tabulated data... more (see page 1795)
The Decision Graph Display (see page 1796)	By default, the decision graph plots summary values for categories in the first active row field (along the y-axis) against values in the first active column field (along the x-axis). Each graphed category appears as a separate series. If only one dimension is selected—for example, by clicking only one *TDecisionPivot* button—only one series is graphed. If you used a decision pivot, you can push its buttons to determine which decision cube fields (dimensions) are graphed. To exchange graph axes, drag the decision pivot dimension buttons from one side of the separator space to the other. If you have a one-dimensional... more (see page 1796)
Using the Decision Cube Editor (see page 1796)	You can use the Decision Cube editor to set the DimensionMap properties of decision cubes. You can display the Decision Cube editor through the **Object Inspector**, as described in the previous section, or by right-clicking a decision cube on a form at design time and choosing Decision Cube editor. The Decision Cube Editor dialog box has two tabs: • Dimension Settings (see page 1794) used to activate or disable available dimensions, rename and reformat dimensions, put dimensions in a permanently drilled state, and set date ranges to display. • Memory Control, used to set the maximum number of dimensions and summaries (see page 1793) that can be... more (see page 1796)
Creating and Using Decision Graphs (see page 1796)	Decision graph components, TDecisionGraph, present cross-tabulated data in graphic form. Each decision graph shows the value of a single summary, such as Sum, Count, or Avg, charted for one or more dimensions. For more information on crosstabs, see One-dimensional crosstabs. (see page 1795) For illustrations of decision graphs at design time, see the figures Decision support components at design time (see page 1790) and Decision graphs bound to different decision sources. (see page 1795) The following topics are discussed in this section: • Creating Decision Graphs (see page 1802) • Using Decision Graphs (see page 1795) • The Decision Graph Display (see page 1796) • Customizing Decision Graphs (see page 1801)
Multidimensional Crosstabs (see page 1797)	Multidimensional crosstabs use additional dimensions for the rows and/or columns. For example, a two-dimensional crosstab could show amounts paid by payment method for each country. A three-dimensional crosstab could show amounts paid by payment method and terms by country, as shown in the following figure. 

Using Decision Cubes (see page 1797)	The decision cube component, TDecisionCube, is a multidimensional data store that fetches its data from a dataset (typically a specially structured SQL statement entered through *TDecisionQuery* or *TQuery*). The data is stored in a form that makes its easy to pivot (that is, change the way in which the data is organized and summarized) without needing to run the query a second time. The following topics are discussed in this section: • Decision Cube Properties and Events (see page 1788) • Using the Decision Cube Editor (see page 1796)
Decision Grid Properties (see page 1798)	The decision grid component, TDecisionGrid, displays data from the TDecisionSource component bound to TDecisionSource. By default, data appears in a grid with category fields on the left side and top of the grid. The following are some special properties that control the appearance and behavior of decision grids: • *TDecisionGrid* has unique properties for each dimension. To set these, choose *Dimensions* in the **Object Inspector**, then select a dimension. Its properties then appear in the **Object Inspector**: *Alignment* defines the alignment of category labels for that dimension, *Caption* can be used to override the default dimension name, *Color* defines... more (see page 1798)
Using Decision Pivots (see page 1798)	The decision pivot component, TDecisionPivot, lets you open or close decision cube dimensions, or fields, by pressing buttons. When a row or column is opened by pressing a *TDecisionPivot* button, the corresponding dimension appears on the TDecisionGrid or TDecisionGraph component. When a dimension is closed, its detailed data doesn't appear; it collapses into the totals of other dimensions. A dimension may also be in a "drilled" state, where only the summaries for a particular value of the dimension field appear. You can also use the decision pivot to reorganize dimensions displayed in the decision grid and decision graph. Just drag... more (see page 1798)
Customizing Decision Graph Series (see page 1799)	The templates supply many defaults for each decision cube dimension, such as graph type and how series are displayed. Other defaults, such as series color, are defined by *TDecisionGraph*. If you want you can override the defaults for each series. The templates are intended for use when you want the program to create the series for categories as they are needed, and discard them when they are no longer needed. If you want, you can set up custom series for specific category values. To do this, pivot the graph so its current display has a series for the category... more (see page 1799)
Using Datasets with Decision Support Components (see page 1799)	The only decision support component that binds directly to a dataset is the decision cube, TDecisionCube. *TDecisionCube* expects to receive data with groups and summaries defined by an SQL statement of an acceptable format. The GROUP BY phrase must contain the same non-summarized fields (and in the same order) as the SELECT phrase, and summary fields must be identified. The decision query component, TDecisionQuery, is a specialized form of *TQuery*. You can use TDecisionQuery (see page 1802) to more simply define the setup of dimensions (rows and columns) and summary values used to supply data to decision cubes (*TDecisionCube*). The... more (see page 1799)
Using Decision Support Components (see page 1800)	The decision support components help you create cross-tabulated—or, crosstab—tables and graphs. You can then use these tables and graphs to view and summarize data from different perspectives. For more information on cross-tabulated data, see About crosstabs. (see page 1804) The following topics are discussed in this section: • Overview of Decision Support Components (see page 1790) • Guidelines for Using Decision Support Components (see page 1804) • Decision Support Components at Runtime (see page 1789) • Decision Support Components and Memory Control (see page 1800)

Decision Support Components and Memory Control (see page 1800)	When a dimension or summary is loaded into the decision cube, it takes up memory. Adding a new summary increases memory consumption linearly: that is, a decision cube with two summaries uses twice as much memory as the same cube with only one summary, a decision cube with three summaries uses three times as much memory as the same cube with one summary, and so on. Memory consumption for dimensions increases more quickly. Adding a dimension with 10 values increases memory consumption by a factor of 10. Adding a dimension with 100 values increases memory consumption 100 times. Thus adding... more (see page 1800)
Using Decision Grids (see page 1801)	The decision grid component, TDecisionGrid, displays data from decision cubes TDecisionCube bound to decision sources TDecisionSource. By default, the grid appears with dimension fields at its left side and/or top, depending on the grouping instructions defined in the dataset. Categories, one for each data value, appear under each field. You can • Open and Close Dimensions (see page 1790) • Reorganize (see page 1792) • Drill Down for Detail (see page 1790) • Limit Dimension Selection to a Single Dimension for Each Axis (see page 1790) For more information about special properties and events of the decision grid, see Decision grid properties. (see page 1798)
Customizing Decision Graphs (see page 1801)	The decision graph component, TDecisionGraph, displays fields from the decision source (TDecisionSource) as a dynamic graph that changes when data dimensions are opened, closed, dragged and dropped, or rearranged with the decision pivot TDecisionPivot. You can change the type, colors, marker types for line graphs, and many other properties of decision graphs.
Creating Decision Graphs (see page 1802)	
Creating Decision Datasets with the Decision Query Editor (see page 1802)	All data used by the decision support components passes through the decision cube, which accepts a specially formatted dataset most easily produced by an SQL query. See Using datasets with decision support components (see page 1799) for more information. While both *TTable* and *TQuery* can be used as decision datasets, it is easier to use TDecisionQuery; the Decision Query editor supplied with it can be used to specify tables, fields, and summaries to appear in the decision cube and will help you set up the SELECT and GROUP BY portions of the SQL correctly.
Using Decision Sources (see page 1803)	The decision source component, TDecisionSource, defines the current pivot state of decision grids or decision graphs. Any two objects which use the same decision source also share pivot states. The following are some special properties and events that control the appearance and behavior of decision sources: • The ControlType property of *TDecisionSource* indicates whether the decision pivot buttons should act like check boxes (multiple selections) or radio buttons (mutually exclusive selections). • The SparseCols and SparseRows properties of *TDecisionSource* indicate whether to display columns or rows with no values; if *True*, sparse columns or rows are displayed. TDecisionSource has the following... more (see page 1803)
Creating and Using Decision Grids (see page 1803)	Decision grid components, TDecisionGrid, present cross-tabulated data in table form. These tables are also called crosstabs, described in About crosstabs. (see page 1804) The figure Decision support components at design time (see page 1790) shows a decision grid on a form at design time. The following topics are discussed in this section: • Creating Decision Grids (see page 1788) • Using Decision Grids (see page 1801) • Decision Grid Properties (see page 1798)

About Crosstabs (see page 1804)	Cross-tabulations, or crosstabs, are a way of presenting subsets of data so that relationships and trends are more visible. Table fields become the dimensions of the crosstab while field values define categories and summaries within a dimension. You can use the decision support components to set up crosstabs in forms. TDecisionGrid shows data in a table, while TDecisionGraph charts it graphically. TDecisionPivot has buttons that make it easier to display and hide dimensions and move them between columns and rows. Crosstabs can be one-dimensional or multidimensional. The following topics are discussed in this section: • One-Dimensional Crosstabs (see page 1795) • Multidimensional Crosstabs (see page 1797)
Guidelines for Using Decision Support Components (see page 1804)	The decision support components listed in Overview of decision support components (see page 1790) can be used together to present multidimensional data as tables and graphs. More than one grid or graph can be attached to each dataset. More than one instance of *TDecisionPivot* can be used to display the data from different perspectives at runtime.

3.2.3.10.1 Changing Other Decision Graph Series Properties

To change color or other properties of a decision graph series

1. Select the Series page at the top of the Chart Editing dialog box.
2. Choose a series in the drop-down list at the top of the page.
3. Choose the appropriate property tab and select settings.
4. Check the Save Series check box.

See Also

Changing the Series Graph Type (see page 1787)

Saving Decision Graph Series Settings (see page 1792)

3.2.3.10.2 Changing Other Decision Graph Template Properties

To change color or other properties of a template

1. Select the Series page at the top of the Chart Editing dialog box.
2. Choose a template in the drop-down list at the top of the page.
3. Choose the appropriate property tab and select settings.

See Also

Changing the Default Decision Graph Type (see page 1786)

Viewing Overall Decision Graph Properties (see page 1794)

3.2.3.10.3 Changing the Default Decision Graph Type

To change the default graph type

1. Select a template in the Series list on the Chart page of the Chart Editing dialog box.
2. Click the Change button.
3. Select a new type and close the Gallery dialog box.

See Also

Changing Other Decision Graph Template Properties (see page 1786)

Viewing Overall Decision Graph Properties (see page 1794)

3.2.3.10.4 Changing the Series Graph Type

By default, each series has the same graph type, defined by the template for its dimension. To change all series to the same graph type, you can change the template type. See Changing other decision graph series properties. (see page 1786) for instructions.

To change the graph type for a single series

1. Select a series in the Series list on the Chart page of the Chart editor.
2. Click the Change button.
3. Select a new type and close the Gallery dialog box.
4. Check the Save Series check box.

See Also

Changing Other Decision Graph Series Properties (see page 1786)

Saving Decision Graph Series Settings (see page 1792)

3.2.3.10.5 Creating Decision Datasets with TQuery or TTable

If you use an ordinary TQuery component as a decision dataset, you must manually set up the SQL statement, taking care to supply a GROUP BY phrase which contains the same fields (and in the same order) as the SELECT phrase.

The SQL should look similar to this:

```
SELECT ORDERS."Terms", ORDERS."ShipVIA",
  ORDERS."PaymentMethod", SUM( ORDERS."AmountPaid" )
FROM "ORDERS.DB" ORDERS
GROUP BY ORDERS."Terms", ORDERS."ShipVIA", ORDERS."PaymentMethod"
```

The ordering of the SELECT fields should match the ordering of the GROUP BY fields. Queries are described in more detail in Using TQuery (see page 1674).

With TTable, you must supply information to the decision cube about which of the fields in the query are grouping fields, and which are summaries. To do this, Fill in the Dimension Type for each field in the *DimensionMap* of the Decision Cube. You must indicate whether each field is a dimension or a summary, and if a summary, you must provide the summary type. Since pivoting averages depend on SUM/COUNT calculations, you must also provide the base field name to allow the decision cube to match pairs of SUM and COUNT aggregators.

See Also

Creating Decision Datasets with the Decision Query Editor (see page 1802)

Working with Tables (see page 1674)

Working with Queries (see page 1674)

3.2.3.10.6 Creating Decision Grids

To create a form with one or more tables of cross-tabulated data

1. Follow steps 1–3 listed under Guidelines for using decision support components. (see page 1804)
2. Add one or more decision grid components (TDecisionGrid) and bind them to the decision source, TDecisionSource, with the **Object Inspector** by setting their DecisionSource property to the appropriate decision source component.
3. Continue with steps 5–7 listed under Guidelines for using decision support components. (see page 1804)

For a description of what appears in the decision grid and how to use it, see Using decision grids. (see page 1801).

To add a graph to the form, follow the instructions in Creating decision graphs. (see page 1796)

See Also

Decision Grid Properties (see page 1798)

3.2.3.10.7 Decision Cube Properties and Events

The DimensionMap properties of *TDecisionCube* not only control which dimensions and summaries appear but also let you set date ranges and specify the maximum number of dimensions the decision cube may support. You can also indicate whether or not to display data during design. You can display names, (categories) values, subtotals, or data. Display of data at design time can be time consuming, depending on the data source.

When you click the ellipsis next to *DimensionMap* in the **Object Inspector**, the Decision Cube editor dialog box appears. You can use its pages and controls to set the *DimensionMap* properties.

The OnRefresh event fires whenever the decision cube cache is rebuilt. Developers can access the new dimension map and change it at that time to free up memory, change the maximum summaries or dimensions, and so on. *OnRefresh* is also useful if users access the Decision Cube editor; application code can respond to user changes at that time.

See Also

Using the Decision Cube Editor (see page 1796)

3.2.3.10.8 Decision Graphs at Runtime

Users can drag from side to side or up and down in the graph grid area to scroll through off-screen categories and values.

See Also

Decision Pivots: Runtime Behavior (see page 1789)

Decision Grids at Runtime (see page 1788)

Using Decision Graphs (see page 1795)

3.2.3.10.9 Decision Grids at Runtime

Users can:

Right-click within the decision grid and choose to:

- Toggle subtotals on and off for individual data groups, for all values of a dimension, or for the whole grid.
- Display the Decision Cube editor, described in Using the Decision Cube editor. (see page 1796)
- Toggle dimensions and summaries open and closed.

Click + and – within the row and column headings to open and close dimensions.

Drag and drop dimensions from rows to columns and the reverse.

See Also

Decision Pivots: Runtime Behavior (see page 1789)

Decision Graphs at Runtime (see page 1788)

Using Decision Grids (see page 1801)

3.2.3.10.10 Decision Pivots: Runtime Behavior

Users can:

Left-click the summary button at the left end of the decision pivot to display a list of available summaries. They can use this list to change the summary data displayed in decision grids and decision graphs.

Right-click a dimension button and choose to:

- Move it from the row area to the column area or the reverse.
- Drill In to display detail data.

Left-click a dimension button following the Drill In command and choose:

- Open Dimension to move back to the top level of that dimension.
- All Values to toggle between displaying just summaries and summaries plus all other values in decision grids.
- From a list of available categories for that dimension, a category to drill into for detail values.

Left-click a dimension button to open or close that dimension.

Drag and drop dimension buttons from the row area to the column area and the reverse; they can drop them next to existing buttons in that area or onto the row or column icon.

See Also

Decision Grids at Runtime (see page 1788)

Decision Graphs at Runtime (see page 1788)

Using Decision Pivots (see page 1799)

3.2.3.10.11 Decision Support Components at Runtime

At runtime, users can perform many operations by left-clicking, right-clicking, and dragging visible decision support components. These operations are summarized below.

- Decision Pivots at Runtime (see page 1789)
- Decision Grids at Runtime (see page 1788)
- Decision Graphs at Runtime (see page 1788)

See Also

Overview of Decision Support Components (see page 1790)

About Crosstabs (see page 1804)

Guidelines for Using Decision Support Components (see page 1804)

Decision Support Components and Memory Control (see page 1800)

3.2.3.10.12 Drilling Down for Detail in Decision Grids

You can drill down to see more detail in a dimension.

For example, if you right-click a category label (row heading) for a dimension with others collapsed beneath it, you can choose to drill down and only see data for that category. When a dimension is drilled, you do not see the category labels for that dimension displayed on the grid, since only the records for a single category value are being displayed. If you have a decision pivot on the form, it displays category values and lets you change to other values if you want.

To drill down into a dimension,

- Right-click a category label and choose Drill In To This Value, or
- Right-click a pivot button and choose Drilled In.

To make the complete dimension active again,

- Right-click the corresponding pivot button or,
- Right-click the decision grid in the upper-left corner and select the dimension.

See Also

Opening and Closing Decision Grid Fields (see page 1790)

Reorganizing Rows and Columns in Decision Grids (see page 1792)

Limiting Dimension Selection in Decision Grids (see page 1790)

3.2.3.10.13 Limiting Dimension Selection in Decision Grids

You can change the *ControlType* property of the decision source to determine whether more than one dimension can be selected for each axis of the grid. For more information, see Using Decision Sources. (see page 1803)

See Also

Opening and Closing Decision Grid Fields (see page 1790)

Reorganizing Rows and Columns in Decision Grids (see page 1792)

Drilling Down for Detail in Decision Grids (see page 1790)

3.2.3.10.14 Opening and Closing Decision Grid Fields

If a plus sign (+) appears in a dimension or summary field, one or more fields to its right are closed (hidden). You can open additional fields and categories by clicking the sign. A minus sign (–) indicates a fully opened (expanded) field. When you click the sign, the field closes. This outlining feature can be disabled; see Decision Grid Properties (see page 1798) for details.

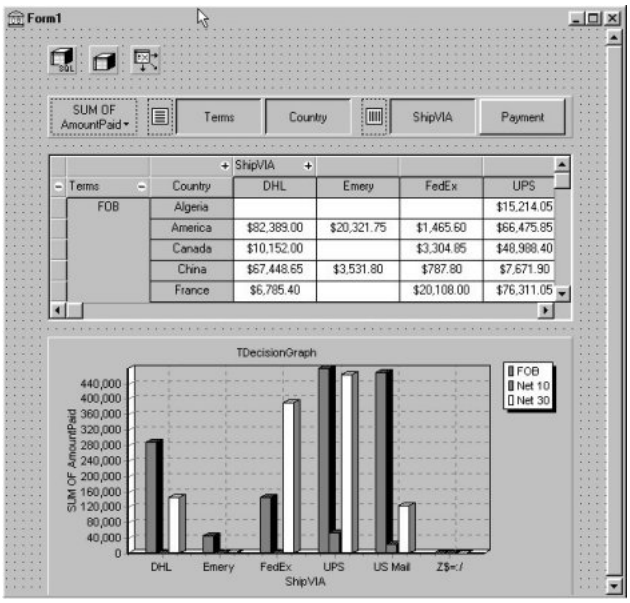
See Also

Reorganizing Rows and Columns in Decision Grids (see page 1792)

Drilling Down for Detail in Decision Grids (see page 1790)

Limiting Dimension Selection in Decision Grids (see page 1790)

3.2.3.10.15 Overview of Decision Support Components



The decision support components appear on the Decision Cube category of the **Tool Palette**:

- The decision cube, TDecisionCube, is a multidimensional data store. For more information see Using decision cubes. (see

page 1797)

- The decision source, TDecisionSource, defines the current pivot state of a decision grid or a decision graph. For more information, see Using decision sources. (see page 1803)
- The decision query, TDecisionQuery, is a specialized form of TQuery used to define the data in a decision cube. For more information, see Using datasets with decision support components. (see page 1799)
- The decision pivot, TDecisionPivot, lets you open or close decision cube dimensions, or fields, by pressing buttons. For more information, see Using decision pivots. (see page 1798)
- The decision grid, TDecisionGrid, displays single- and multidimensional data in table form. For more information, see Creating and using decision grids. (see page 1803)
- The decision graph, TDecisionGraph, displays fields from a decision grid as a dynamic graph that changes when data dimensions are modified. For more information, see Creating and using decision graphs. (see page 1796)

The following figure shows all the decision support components placed on a form at design time.

See Also

Guidelines for Using Decision Support Components (see page 1804)

Decision Support Components and Memory Control (see page 1800)

3.2.3.10.16 Decision Pivot Properties

The following are some special properties that control the appearance and behavior of decision pivots:

- The first properties listed for *TDecisionPivot* define its overall behavior and appearance. You might want to set *ButtonAutoSize* to *False* for *TDecisionPivot* to keep buttons from expanding and contracting as you adjust the size of the component.
- The *Groups* property of *TDecisionPivot* defines which dimension buttons appear. You can display the row, column, and summary selection button groups in any combination. Note that if you want more flexibility over the placement of these groups, you can place one *TDecisionPivot* on your form which contains only rows in one location, and a second which contains only columns in another location.
- Typically, *TDecisionPivot* is added above *TDecisionGrid*. In its default orientation, horizontal, buttons on the left side of *TDecisionPivot* apply to fields on the left side of *TDecisionGrid* (rows); buttons on the right side apply to fields at the top of *TDecisionGrid* (columns).
- You can determine where *TDecisionPivot*'s buttons appear by setting its GroupLayout property to *xtVertical*, *xtLeftTop*, or

xtHorizontal (the default, described in the previous paragraph).

3.2.3.10.17 Reorganizing Rows and Columns in Decision Grids

You can drag row and column headings to new locations within the same axis or to the other axis. In this way, you can reorganize the grid and see the data from new perspectives as the data groupings change. This pivoting feature can be disabled; see Decision Grid Properties (see page 1798) for details.

If you included a decision pivot, you can push and drag its buttons to reorganize the display. See Using decision Pivots (see page 1798) for instructions.

See Also

Opening and Closing Decision Grid Fields (see page 1790)

Drilling Down for Detail in Decision Grids (see page 1790)

Limiting Dimension Selection in Decision Grids (see page 1790)

3.2.3.10.18 Saving Decision Graph Series Settings

By default, only settings for templates are saved at design time. Changes made to specific series are only saved if the Save box is checked for that series in the **Chart Editing** dialog box.

Saving series can be memory intensive, so if you don't need to save them you can uncheck the Save box.

See Also

Changing the Series Graph Type (see page 1787)

Changing Other Decision Graph Series Properties (see page 1786)

3.2.3.10.19 Setting Decision Graph Template Defaults

Decision graphs display the values from two dimensions of the decision cube: one dimension is displayed as an axis of the graph, and the other is used to create a set of series. The template for that dimension provides default properties for those series (such as whether the series are bar, line, area, and so on). As users pivot from one state to another, any required series for the dimension are created using the series type and other defaults specified in the template.

A separate template is provided for cases where users pivot to a state where only one dimension is active. A one-dimensional state is often represented with a pie chart, so a separate template is provided for this case.

You can

- Change the default graph type. (see page 1786)
- Change other graph template properties. (see page 1786)
- View and set overall graph properties. (see page 1794)

See Also

Customizing Decision Graph Series (see page 1799)

3.2.3.10.20 Setting Dimension State

The *ActiveFlag* property controls which dimensions get loaded. You can set this property on the Dimension Settings tab of the Decision Cube editor using the Activity Type control. When this control is set to *Active*, the dimension is loaded unconditionally, and will always take up space. Note that the number of dimensions in this state must always be less than *MaxDimensions*, and

the number of summaries set to *Active* must be less than *MaxSummaries*. You should set a dimension or summary to *Active* only when it is critical that it be available at all times. An *Active* setting decreases the ability of the cube to manage the available memory.

When *ActiveFlag* is set to *AsNeeded*, a dimension or summary is loaded only if it can be loaded without exceeding the *MaxDimensions*, *MaxSummaries*, or *MaxCells* limit. The decision cube will swap dimensions and summaries that are marked *AsNeeded* in and out of memory to keep within the limits imposed by *MaxCells*, *MaxDimensions*, and *MaxSummaries*. Thus, a dimension or summary may not be loaded in memory if it is not currently being used. Setting dimensions that are not used frequently to *AsNeeded* results in better loading and pivoting performance, although there will be a time delay to access dimensions which are not currently loaded.

See Also

Setting Maximum Dimensions (see page 1793)

Using Paged Dimensions (see page 1793)

3.2.3.10.21 Setting Maximum Dimensions, Summaries, and Cells

The decision cube's *MaxDimensions* and *MaxSummaries* properties can be used with the *CubeDim.ActiveFlag* property to control how many dimensions and summaries can be loaded at a time. You can set the maximum values on the Cube Capacity page of the Decision Cube editor to place some overall control on how many dimensions or summaries can be brought into memory at the same time.

Limiting the number of dimensions or summaries provides a rough limit on the amount of memory used by the decision cube. However, it does not distinguish between dimensions with many values and those with only a few. For greater control of the absolute memory demands of the decision cube, you can also limit the number of cells in the cube. Set the maximum number of cells on the Cube Capacity page of the Decision Cube editor.

See Also

Setting Dimension State (see page 1792)

Using Paged Dimensions (see page 1793)

3.2.3.10.22 Setting the Maximum Available Dimensions and Summaries

To determine the maximum number of dimensions and summaries available for decision pivots, decision grids, and decision graphs bound to the selected decision cube, display the Decision Cube editor and click the Memory Control tab. Use the edit controls to adjust the current settings, if necessary. These settings help to control the amount of memory required by the decision cube. For more information, see Decision Support Components and Memory Control. (see page 1800)

See Also

Viewing and Changing Dimension Settings (see page 1794)

Viewing and Changing Design Options (see page 1794)

3.2.3.10.23 Using Paged Dimensions

When Binning is set to Set on the Dimension Settings tab of the Decision cube editor and Start Value is not NULL, the dimension is said to be "paged," or "permanently drilled down." You can access data for just a single value of that dimension at a time, although you can programmatically access a series of values sequentially. Such a dimension may not be pivoted or opened.

It is extremely memory intensive to include dimensional data for dimensions that have very large numbers of values. By making such dimensions paged, you can display summary information for one value at a time. Information is usually easier to read when

displayed this way, and memory consumption is much easier to manage.

See Also

Setting Maximum Dimensions (see page 1793)

Setting Dimension State (see page 1792)

3.2.3.10.24 Viewing and Changing Design Options

To determine how much information appears at design time, display the Decision Cube editor and click the Memory Control tab. Then, check the setting that indicates which names and data to display. Display of data or field names at design time can cause performance delays in some cases because of the time needed to fetch the data.

See Also

Viewing and Changing Dimension Settings (see page 1794)

Setting the Maximum Available Dimensions and Summaries (see page 1793)

3.2.3.10.25 Viewing and Changing Dimension Settings

To view the dimension settings, display the Decision Cube editor and click the Dimension Settings tab. Then, select a dimension or summary in the Available Fields list. Its information appears in the boxes on the right side of the editor:

- To change the dimension or summary name that appears in the decision pivot, decision grid, or decision graph, enter a new name in the Display Name edit box.
- To determine whether the selected field is a dimension or summary, read the text in the Type edit box. If the dataset is a *TTable* component, you can use Type to specify whether the selected field is a dimension or summary.
- To disable or activate the selected dimension or summary, change the setting in the Active Type drop-down list box: Active, As Needed, or Inactive. Disabling a dimension or setting it to As Needed saves memory.
- To change the format of that dimension or summary, enter a format string in the Format edit box.
- To display that dimension or summary by Year, Quarter, or Month, change the setting in the Binning drop-down list box. Note that you can choose Set in the Binning list box to put the selected dimension or summary in a permanently "drilled down" state. This can be useful for saving memory when a dimension has many values. For more information, see Decision support components and memory control. (see page 1800)
- To determine the starting value for ranges, or the drill-down value for a "Set" dimension, first choose the appropriate Grouping value in the Grouping drop-down, and then enter the starting range value or permanent drill-down value in the Initial Value drop-down list.

See Also

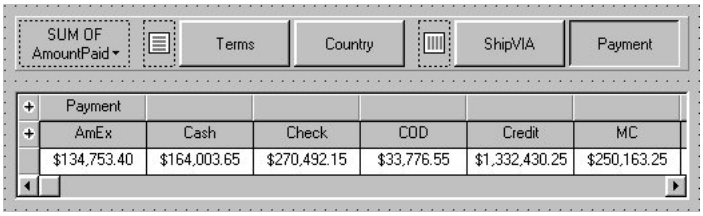
Setting the Maximum Available Dimensions and Summaries (see page 1793)

Viewing and Changing Design Options (see page 1794)

3.2.3.10.26 Viewing Overall Decision Graph Properties

To view and set decision graph properties other than type and series

1. Select the Chart page at the top of the Chart Editing dialog box.
2. Choose the appropriate property tab and select settings.



See Also

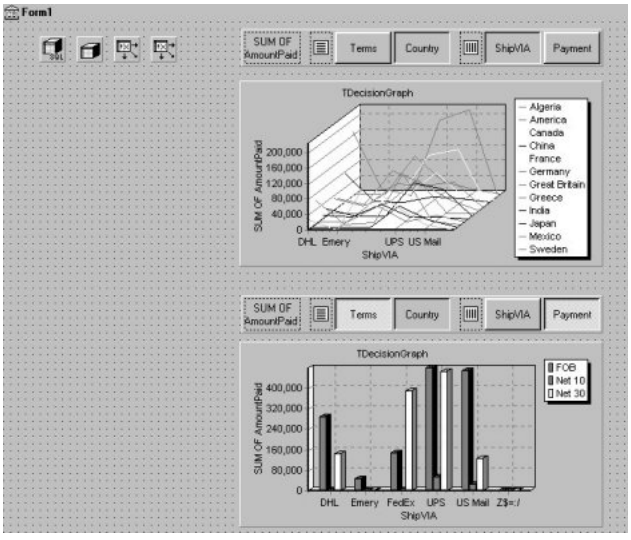
Changing the Default Decision Graph Type (see page 1786)

Changing Other Decision Graph Template Properties (see page 1786)

3.2.3.10.27 One-Dimensional Crosstabs

One-dimensional crosstabs show a summary row (or column) for the categories of a single dimension. For example, if Payment is the chosen column dimension and Amount Paid is the summary category, the crosstab in the following figure shows the amount paid using each method.

3.2.3.10.28 Using Decision Graphs



The decision graph component, TDecisionGraph, displays fields from the decision source TDecisionSource as a dynamic graph that changes when data dimensions are opened, closed, dragged and dropped, or rearranged with the decision pivot TDecisionPivot.

Graphed data comes from a specially formatted dataset such as TDecisionQuery. For an overview of how the decision support components handle and arrange this data, see Using Decision Support Components. (see page 1800)

By default, the first row dimension appears as the x-axis and the first column dimension appears as the y-axis.

You can use decision graphs instead of or in addition to decision grids, which present cross-tabulated data in tabular form. Decision grids and decision graphs that are bound to the same decision source present the same data dimensions. To show different summary data for the same dimensions, you can bind more than one decision graph to the same decision source. To show different dimensions, bind decision graphs to different decision sources.

For example, in the following figure the first decision pivot and graph are bound to the first decision source and the second decision pivot and graph are bound to the second. So, each graph can show different dimensions.

For more information about what appears in a decision graph, see the next section, The Decision Graph Display. (see page 1796)

To create a decision graph, see the previous section, Creating Decision Graphs. (see page 1802)

For a discussion of decision graph properties and how to change the appearance and behavior of decision graphs, see Customizing Decision Graphs. (see page 1801)

See Also

Using Decision Grids (see page 1801)

3.2.3.10.29 The Decision Graph Display

By default, the decision graph plots summary values for categories in the first active row field (along the y-axis) against values in the first active column field (along the x-axis). Each graphed category appears as a separate series.

If only one dimension is selected—for example, by clicking only one *TDecisionPivot* button—only one series is graphed.

If you used a decision pivot, you can push its buttons to determine which decision cube fields (dimensions) are graphed. To exchange graph axes, drag the decision pivot dimension buttons from one side of the separator space to the other. If you have a one-dimensional graph with all buttons on one side of the separator space, you can use the Row or Column icon as a drop target for adding buttons to the other side of the separator and making the graph multidimensional.

If you only want one column and one row to be active at a time, you can set the *ControlType* property for *TDecisionSource* to *xtRadio*. Then, there can be only one active field at a time for each decision cube axis, and the decision pivot's functionality will correspond to the graph's behavior. *xtRadioEx* works the same as *xtRadio*, but does not allow the state where all row or all columns dimensions are closed.

When you have both a decision grid and graph connected to the same *TDecisionSource*, you'll probably want to set *ControlType* back to *xtCheck* to correspond to the more flexible behavior of *TDecisionGrid*.

See Also

Creating Decision Graphs (see page 1802)

Using Decision Graphs (see page 1795)

Customizing Decision Graphs (see page 1801)

3.2.3.10.30 Using the Decision Cube Editor

You can use the Decision Cube editor to set the DimensionMap properties of decision cubes. You can display the Decision Cube editor through the **Object Inspector**, as described in the previous section, or by right-clicking a decision cube on a form at design time and choosing Decision Cube editor.

The Decision Cube Editor dialog box has two tabs:

- Dimension Settings (see page 1794) used to activate or disable available dimensions, rename and reformat dimensions, put dimensions in a permanently drilled state, and set date ranges to display.
- Memory Control, used to set the maximum number of dimensions and summaries (see page 1793) that can be active at one time, to display information about memory usage, and to determine the names and data that appear at design time. (see page 1794)

See Also

Decision Cube Properties and Events (see page 1788)

3.2.3.10.31 Creating and Using Decision Graphs

Decision graph components, TDecisionGraph, present cross-tabulated data in graphic form. Each decision graph shows the

value of a single summary, such as Sum, Count, or Avg, charted for one or more dimensions. For more information on crosstabs, see One-dimensional crosstabs. (see page 1795) For illustrations of decision graphs at design time, see the figures Decision support components at design time (see page 1790) and Decision graphs bound to different decision sources. (see page 1795)

The following topics are discussed in this section:

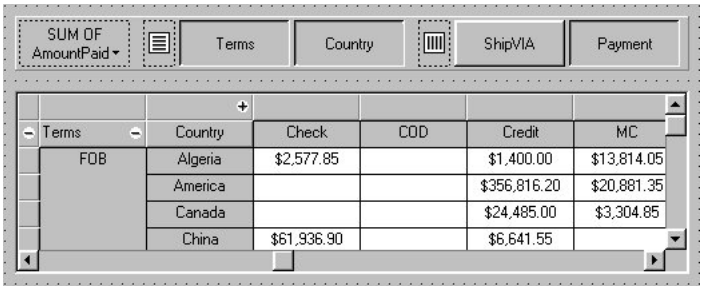
- Creating Decision Graphs (see page 1802)
- Using Decision Graphs (see page 1795)
- The Decision Graph Display (see page 1796)
- Customizing Decision Graphs (see page 1801)

See Also

Using Datasets with Decision Support Components (see page 1799)

Using Decision Cubes (see page 1797)

Using Decision Sources (see page 1803)



Using Decision Pivots (see page 1799)

Creating and Using Decision Grids (see page 1803)

3.2.3.10.32 Multidimensional Crosstabs

Multidimensional crosstabs use additional dimensions for the rows and/or columns. For example, a two-dimensional crosstab could show amounts paid by payment method for each country.

A three-dimensional crosstab could show amounts paid by payment method and terms by country, as shown in the following figure.

3.2.3.10.33 Using Decision Cubes

The decision cube component, TDecisionCube, is a multidimensional data store that fetches its data from a dataset (typically a specially structured SQL statement entered through *TDecisionQuery* or *TQuery*). The data is stored in a form that makes its easy to pivot (that is, change the way in which the data is organized and summarized) without needing to run the query a second time.

The following topics are discussed in this section:

- Decision Cube Properties and Events (see page 1788)
- Using the Decision Cube Editor (see page 1796)

See Also

Using Datasets with Decision Support Components (see page 1799)

Using Decision Sources (see page 1803)

Using Decision Pivots (see page 1799)

Creating and Using Decision Grids (see page 1803)

Creating and Using Decision Graphs (see page 1796)

3.2.3.10.34 Decision Grid Properties

The decision grid component, TDecisionGrid, displays data from the TDecisionSource component bound to TDecisionSource. By default, data appears in a grid with category fields on the left side and top of the grid.

The following are some special properties that control the appearance and behavior of decision grids:

- *TDecisionGrid* has unique properties for each dimension. To set these, choose *Dimensions* in the **Object Inspector**, then select a dimension. Its properties then appear in the **Object Inspector**: *Alignment* defines the alignment of category labels for that dimension, *Caption* can be used to override the default dimension name, *Color* defines the color of category labels, *FieldName* displays the name of the active dimension, *Format* can hold any standard format for that data type, and *Subtotals* indicates whether to display subtotals for that dimension. With summary fields, these same properties are used to changed the appearance of the data that appears in the summary area of the grid. When you're through setting dimension properties, either click a component in the form or choose a component in the drop-down list box at the top of the **Object Inspector**.
- The *Options* property of TDecisionGrid lets you control display of grid lines (*cgGridLines* = *True*), enabling of outline features (collapse and expansion of dimensions with + and - indicators; *cgOutliner* = *True*), and enabling of drag-and-drop pivoting (*cgPivotable* = *True*).
- The *OnDecisionDrawCell* event of *TDecisionGrid* gives you a chance to change the appearance of each cell as it is drawn. The event passes the *String*, *Font*, and *Color* of the current cell as reference parameters. You are free to alter those parameters to achieve effects such as special colors for negative values. In addition to the *DrawState* which is passed by *TCustomGrid*, the event passes *TDecisionDrawState*, which can be used to determine what type of cell is being drawn. Further information about the cell can be fetched using the *Cells*, *CellValueArray*, or *CellDrawState* functions.
- The *OnDecisionExamineCell* event of *TDecisionGrid* lets you hook the right-click-on-event to data cells, and is intended to allow a program to display information (such as detail records) about that particular data cell. When the user right-clicks a data cell, the event is supplied with all the information which is was used to compose the data value, including the currently active summary value and a *ValueArray* of all the dimension values which were used to create the summary value.

See Also

Creating Decision Grids (see page 1788)

Using Decision Grids (see page 1801)

3.2.3.10.35 Using Decision Pivots

The decision pivot component, TDecisionPivot, lets you open or close decision cube dimensions, or fields, by pressing buttons. When a row or column is opened by pressing a *TDecisionPivot* button, the corresponding dimension appears on the TDecisionGrid or TDecisionGraph component. When a dimension is closed, its detailed data doesn't appear; it collapses into the totals of other dimensions. A dimension may also be in a "drilled" state, where only the summaries for a particular value of the dimension field appear.

You can also use the decision pivot to reorganize dimensions displayed in the decision grid and decision graph. Just drag a button to the row or column area or reorder buttons within the same area.

For illustrations of decision pivots at design time, see the figures in Decision Support Components at Design Time (see page 1790)One-dimensional Crosstab (see page 1795) and Three-dimensional Crosstab. (see page 1797)

For information on special properties of TDecisionPivot, see Decision Pivot Properties. (see page 1791)

See Also

Using Decision Cubes (see page 1797)

Using Decision Sources (see page 1803)

Creating and Using Decision Grids (see page 1803)

Creating and Using Decision Graphs (see page 1796)

3.2.3.10.36 Customizing Decision Graph Series

The templates supply many defaults for each decision cube dimension, such as graph type and how series are displayed. Other defaults, such as series color, are defined by *TDecisionGraph*. If you want you can override the defaults for each series.

The templates are intended for use when you want the program to create the series for categories as they are needed, and discard them when they are no longer needed. If you want, you can set up custom series for specific category values. To do this, pivot the graph so its current display has a series for the category you want to customize. When the series is displayed on the graph, you can use the Chart editor to

- Change the Graph Type. (see page 1787)
- Change Other Series Properties. (see page 1786)
- Save Specific Graph Series that You Have Customized. (see page 1792)

To define series templates and set overall graph defaults, see Setting Decision Graph Template Defaults. (see page 1792)

3.2.3.10.37 Using Datasets with Decision Support Components

The only decision support component that binds directly to a dataset is the decision cube, TDecisionCube. *TDecisionCube* expects to receive data with groups and summaries defined by an SQL statement of an acceptable format. The GROUP BY phrase must contain the same non-summarized fields (and in the same order) as the SELECT phrase, and summary fields must be identified.

The decision query component, TDecisionQuery, is a specialized form of *TQuery*. You can use TDecisionQuery (see page 1802) to more simply define the setup of dimensions (rows and columns) and summary values used to supply data to decision cubes (*TDecisionCube*). The decision query has no properties than are not inherited from other components. Important inherited properties are Active and SQL.

You can also use a TQuery or TTable component (see page 1787) as a dataset for *TDecisionCube*, but the correct setup of the dataset and TDecisionCube are then the responsibility of the designer.

To work correctly with the decision cube, all projected fields in the dataset must either be dimensions or summaries. The summaries should be additive values (like sum or count), and should represent totals for each combination of dimension values. For maximum ease of setup, sums should be named "Sum..." in the dataset while counts should be named "Count...".

The Decision Cube can pivot, subtotal, and drill-in correctly only for summaries whose cells are additive. (SUM and COUNT are additive, while AVERAGE, MAX, and MIN are not.) Build pivoting crosstab displays only for grids that contain only additive aggregators. If you are using non-additive aggregators, use a static decision grid that does not pivot, drill, or subtotal.

Since averages can be calculated using SUM divided by COUNT, a pivoting average is added automatically when SUM and COUNT dimensions for a field are included in the dataset. Use this type of average in preference to an average calculated using an AVERAGE statement.

Averages can also be calculated using COUNT(*). To use COUNT(*) to calculate averages, include a "COUNT(*) COUNTALL" selector in the query. If you use COUNT(*) to calculate averages, the single aggregator can be used for all fields. Use COUNT(*) only in cases where none of the fields being summarized include blank values, or where a COUNT aggregator is not available for every field.

3.2.3.10.39 Decision Support Components and Memory Control

When a dimension or summary is loaded into the decision cube, it takes up memory. Adding a new summary increases memory consumption linearly: that is, a decision cube with two summaries uses twice as much memory as the same cube with only one summary, a decision cube with three summaries uses three times as much memory as the same cube with one summary, and so on. Memory consumption for dimensions increases more quickly. Adding a dimension with 10 values increases memory consumption by a factor of 10. Adding a dimension with 100 values increases memory consumption 100 times. Thus adding dimensions to a decision cube can have a dramatic effect on memory use, and can quickly lead to performance problems. This effect is especially pronounced when adding dimensions that have many values.

Memory consumption can be limited by the following techniques:

- Setting maximum Dimensions (see page 1793)
- Setting Dimension State (see page 1792)
- Using Paged Dimensions (see page 1793)

The decision support components have a number of settings to help you control how and when memory is used. For more

information on the properties and techniques mentioned here, see TDecisionCube.

Overview of Decision Support Components (see page 1790)

About Crosstabs (see page 1804)

Guidelines for Using Decision Support Components (see page 1804)

Decision Support Components at Runtime (see page 1789)

3.2.3.10.40 Using Decision Grids

The decision grid component, TDecisionGrid, displays data from decision cubes TDecisionCube bound to decision sources TDecisionSource.

By default, the grid appears with dimension fields at its left side and/or top, depending on the grouping instructions defined in the dataset. Categories, one for each data value, appear under each field. You can

- Open and Close Dimensions (see page 1790)
- Reorganize (see page 1792)
- Drill Down for Detail (see page 1790)
- Limit Dimension Selection to a Single Dimension for Each Axis (see page 1790)

For more information about special properties and events of the decision grid, see Decision grid properties. (see page 1798)

See Also

Creating Decision Grids (see page 1788)

3.2.3.10.41 Customizing Decision Graphs

The decision graph component, TDecisionGraph, displays fields from the decision source (TDecisionSource) as a dynamic graph that changes when data dimensions are opened, closed, dragged and dropped, or rearranged with the decision pivot TDecisionPivot. You can change the type, colors, marker types for line graphs, and many other properties of decision graphs.

To customize a graph

1. Right-click it and choose Edit Chart. The Chart Editing dialog box appears.
2. Use the Chart page of the Chart Editing dialog box to view a list of visible series, select the series definition to use when two or more are available for the same series, change graph types for a template or series, and set overall graph properties. The Series list on the Chart page shows all decision cube dimensions (preceded by Template:) and currently visible categories. Each category, or series, is a separate object. You can:

- Add or delete series derived from existing decision-graph series. Derived series can provide annotations for existing series or represent values calculated from other series.
- Change the default graph type, and change the title of templates and series.

3. Use the Series page to establish dimension templates, then customize properties for each individual graph series.

By default, all series are graphed as bar graphs and up to 16 default colors are assigned. You can edit the template type and properties to create a new default. Then, as you pivot the decision source to different states, the template is used to dynamically create the series for each new state. For template details, see Setting decision graph template defaults. (see page 1792).

To customize individual series, follow the instructions in Customizing decision graph series. (see page 1799)

3.2.3.10.42 Creating Decision Graphs

To create a form with one or more decision graphs

1. Follow steps 1–3 listed under Guidelines for using decision support components. (see page 1804)
2. Add one or more decision graph components TDecisionGraph and bind them to the decision source, TDecisionSource, with the **Object Inspector** by setting their *DecisionSource* property to the appropriate decision source component.
3. Continue with steps 5–7 listed under Guidelines for using decision support components. (see page 1804)
4. Finally, right-click the graph and choose Edit Chart to modify the appearance of the graph series. You can set template properties for each graph dimension, then set individual series properties to override these defaults. For details, see Customizing decision graphs. (see page 1801)

For a description of what appears in the decision graph and how to use it, see Using decision graphs. (see page 1795)

To add a decision grid—or crosstab table—to the form, follow the instructions in Creating and using decision grids. (see page 1803)

See Also

The Decision Graph Display (see page 1796)

3.2.3.10.43 Creating Decision Datasets with the Decision Query Editor

All data used by the decision support components passes through the decision cube, which accepts a specially formatted dataset most easily produced by an SQL query. See Using datasets with decision support components (see page 1799) for more information.

While both *TTable* and *TQuery* can be used as decision datasets, it is easier to use TDecisionQuery; the Decision Query editor supplied with it can be used to specify tables, fields, and summaries to appear in the decision cube and will help you set up the SELECT and GROUP BY portions of the SQL correctly.

To use the Decision Query editor

1. Select the decision query component on the form, then right-click and choose Decision Query editor. The Decision Query editor dialog box appears.
2. Choose the database to use.
3. For single-table queries, click the Select Table button. For more complex queries involving multi-table joins, click the Query Builder button to display the SQL Builder or type the SQL statement into the edit box on the SQL tab page.
4. Return to the Decision Query editor dialog box.
5. In the Decision Query editor dialog box, select fields in the Available Fields list box and assign them to be either Dimensions or Summaries by clicking the appropriate right arrow button. As you add fields to the Summaries list, select from the menu displayed the type of summary to use: sum, count, or average.
6. By default, all fields and summaries defined in the SQL property of the decision query appear in the Active Dimensions and Active Summaries list boxes. To remove a dimension or summary, select it in the list and click the left arrow beside the list, or double-click the item to remove. To add it back, select it in the Available Fields list box and click the appropriate right arrow.

Once you define the contents of the decision cube, you can further manipulate dimension display with its *DimensionMap* property and the buttons of *TDecisionPivot*. For more information, see Using decision cubes (see page 1797),Using decision sources (see page 1803), and Using decision pivots (see page 1798).

Note: When you use the Decision Query editor, the query is initially handled in ANSI-92 SQL syntax, then translated (if necessary) into the dialect used by the server. The Decision Query editor reads and displays only ANSI standard SQL. The

dialect translation is automatically assigned to the *TDecisionQuery*'s SQL property. To modify a query, edit the ANSI-92 version in the Decision Query rather then the SQL property.

See Also

Creating Decision Datasets with TQuery or TTable (see page 1787)

3.2.3.10.44 Using Decision Sources

The decision source component, TDecisionSource, defines the current pivot state of decision grids or decision graphs. Any two objects which use the same decision source also share pivot states.

The following are some special properties and events that control the appearance and behavior of decision sources:

- The ControlType property of *TDecisionSource* indicates whether the decision pivot buttons should act like check boxes (multiple selections) or radio buttons (mutually exclusive selections).
- The SparseCols and SparseRows properties of *TDecisionSource* indicate whether to display columns or rows with no values; if *True*, sparse columns or rows are displayed.

TDecisionSource has the following events:

- OnLayoutChange occurs when the user performs pivots or drill-downs that reorganize the data.
- OnNewDimensions occurs when the data is completely altered, such as when the summary or dimension fields are altered.
- OnSummaryChange occurs when the current summary is changed.
- OnStateChange occurs when the Decision Cube activates or deactivates.
- OnBeforePivot occurs when changes are committed but not yet reflected in the user interface. Developers have an opportunity to make changes, for example, in capacity or pivot state, before application users see the result of their previous action.
- OnAfterPivot fires after a change in pivot state. Developers can capture information at that time.

3.2.3.10.45 Creating and Using Decision Grids

Decision grid components, TDecisionGrid, present cross-tabulated data in table form. These tables are also called crosstabs, described in About crosstabs. (see page 1804) The figure Decision support components at design time (see page 1790) shows a decision grid on a form at design time.

The following topics are discussed in this section:

- Creating Decision Grids (see page 1788)
- Using Decision Grids (see page 1801)
- Decision Grid Properties (see page 1798)

Creating and Using Decision Graphs (see page 1796)

3.2.3.10.46 About Crosstabs

Cross-tabulations, or crosstabs, are a way of presenting subsets of data so that relationships and trends are more visible. Table fields become the dimensions of the crosstab while field values define categories and summaries within a dimension.

You can use the decision support components to set up crosstabs in forms. TDecisionGrid shows data in a table, while TDecisionGraph charts it graphically. TDecisionPivot has buttons that make it easier to display and hide dimensions and move them between columns and rows.

Crosstabs can be one-dimensional or multidimensional.

The following topics are discussed in this section:

- One-Dimensional Crosstabs (see page 1795)
- Multidimensional Crosstabs (see page 1797)

Decision Support Components at Runtime (see page 1789)

Decision Support Components and Memory Control (see page 1800)

3.2.3.10.47 Guidelines for Using Decision Support Components

The decision support components listed in Overview of decision support components (see page 1790) can be used together to present multidimensional data as tables and graphs. More than one grid or graph can be attached to each dataset. More than one instance of *TDecisionPivot* can be used to display the data from different perspectives at runtime.

To create a form with tables and graphs of multidimensional data

1. Create a form.
2. Add these components to the form and use the **Object Inspector** to bind them as indicated:

- A dataset, usually *TDecisionQuery* (for details, see Creating Decision Datasets with The Decision Query Editor (see page 1802)) or TQuery
- A decision cube, *TDecisionCube*, bound to the dataset by setting its DataSet property to the dataset's name
- A decision source, *TDecisionSource*, bound to the decision cube by setting its *DecisionCube* property to the decision cube's name

3. Add a decision pivot, *TDecisionPivot*, and bind it to the decision source with the **Object Inspector** by setting its *DecisionSource* property to the appropriate decision source name. The decision pivot is optional but useful; it lets the form developer and end users change the dimensions displayed in decision grids or decision graphs by pushing buttons. In its default orientation, horizontal, buttons on the left side of the decision pivot apply to fields on the left side of the decision grid (rows); buttons on the right side apply to fields at the top of the decision grid (columns). You can determine where the decision pivot's buttons appear by setting its GroupLayout property to *xtVertical*, *xtLeftTop*, or *xtHorizontal* (the default). For more information on decision pivot properties, see Using decision pivots. (see page 1798)
4. Add one or more decision grids and graphs, bound to the decision source. For details, see Creating and using decision grids (see page 1803) and Creating and using decision graphs (see page 1796).

5. Use the Decision Query editor or SQL property of *TDecisionQuery* (or *TQuery*) to specify the tables, fields, and summaries to display in the grid or graph. The last field of the SQL SELECT should be the summary field. The other fields in the SELECT must be GROUP BY fields. For instructions, see Creating decision datasets with the Decision Query editor (see page 1802).
6. Set the *Active* property of the decision query (or alternate dataset component) to *True*.
7. Use the decision grid and graph to show and chart different data dimensions. See Using decision grids (see page 1803) and Using decision graphs. (see page 1796) for instructions and suggestions

For an illustration of all decision support components on a form, see the figure Decision support components at design time. (see page 1790)

3.2.3.11 Using provider components

Topics

Name	Description
Responding to Client Update Requests (see page 1808)	A provider applies updates to database records based on a *Delta* data packet received from a client dataset or XML broker. The client requests updates by calling the ApplyUpdates method (indirectly, through the *IAppServer* interface). As with all method calls made through the *IAppServer* interface, the provider can communicate persistent state information (see page 1540) with a client dataset before and after the call to *ApplyUpdates*. This communication takes place using the BeforeApplyUpdates and AfterApplyUpdates event handlers. If you are using a dataset provider, a number of additional events allow you more control: When a dataset provider receives an update request, it... more (see page 1808)
Adding Custom Information to Data Packets (see page 1808)	Dataset providers can add application-defined information to data packets using the OnGetDataSetProperties event. This information is encoded as an OleVariant, and stored under a name you specify. Client datasets can then retrieve the information using their GetOptionalParam method. You can also specify that the information be included in delta packets that the client dataset sends when updating records. In this case, the client dataset may never be aware of the information, but the provider can send a round-trip message to itself. When adding custom information in the *OnGetDataSetProperties* event, each individual attribute (sometimes called an "optional parameter") is specified using... more (see page 1808)
Applying Updates to Datasets That do Not Represent a Single Table (see page 1809)	When a dataset provider generates SQL statements that apply updates directly to a database server, it needs the name of the database table that contains the records. This can be handled automatically for many datasets such as table type datasets or "live" *TQuery* components. Automatic updates are a problem however, if the provider must apply updates to the data underlying a stored procedure with a result set or a multi-table query. There is no easy way to obtain the name of the table to which updates should be applied. If the query or stored procedure is a BDE-enabled dataset (... more (see page 1809)
Choosing How to Apply Updates Using a Dataset Provider (see page 1810)	*TXMLTransformProvider* components always apply updates to the associated XML document. When using *TDataSetProvider*, however, you can choose how updates are applied. By default, when *TDataSetProvider* components apply updates and resolve update errors, they communicate directly with the database server using dynamically generated SQL statements. This approach has the advantage that your server application does not need to merge updates twice (first to the dataset, and then to the remote server). However, you may not always want to take this approach. For example, you may want to use some of the events on the dataset component. Alternately, the dataset you... more (see page 1810)

Communicating with the Client Dataset (see page 1811)	All communication between a provider and a client dataset or XML broker takes place through an IAppServer interface. If the provider is in the same application as the client, this interface is implemented by a hidden object generated automatically for you, or by a TLocalConnection component. If the provider is part of a multi-tiered application, this is the interface for the application server's remote data module or (in the case of a SOAP server) an interface generated by the connection component. Most applications do not use *IAppServer* directly, but invoke it indirectly through the properties and methods of the client... more (see page 1811)
Controlling What Information Is Included in Data Packets (see page 1812)	When working with a dataset provider, there are a number of ways to control what information is included in data packets that are sent to and from the client. These include • Specifying what fields appear in data packets (see page 1819) • Setting options that influence the data packets (see page 1818) • Adding custom information to data packets (see page 1808) **Note:** These techniques for controlling the content of data packets are only available for dataset providers. When using *TXMLTransformProvider*, you can only control the content of data packets by controlling the transformation file the provider uses.
Determining the Source of Data (see page 1812)	When you use a provider component, you must specify the source it uses to get the data it assembles into data packets. Depending on your version of Delphi, you can specify the source as one of the following: • To provide the data from a dataset, use TDataSetProvider. • To provide the data from an XML document, use TXMLTransformProvider.
Editing Delta Packets Before Updating the Database (see page 1813)	Before a dataset provider applies updates to the database, it generates an OnUpdateData event. The *OnUpdateData* event handler receives a copy of the *Delta* packet as a parameter. This is a client dataset. In the *OnUpdateData* event handler, you can use any of the properties and methods of the client dataset to edit the *Delta* packet before it is written to the dataset. One particularly useful property is the UpdateStatus property. *UpdateStatus* indicates what type of modification the current record in the delta packet represents. It can have any of the values in the following table: ***UpdateStatus values***
Handling Server Constraints (see page 1814)	Most relational database management systems implement constraints on their tables to enforce data integrity. A constraint is a rule that governs data values in tables and columns, or that governs data relationships across columns in different tables. For example, most SQL-92 compliant relational databases support the following constraints: • NOT NULL, to guarantee that a value supplied to a column has a value. • NOT NULL UNIQUE, to guarantee that column value has a value and does not duplicate any other value already in that column for another record. • CHECK, to guarantee that a value supplied to a column falls within a... more (see page 1814)
Influencing How Updates Are Applied (see page 1815)	The OnUpdateData event gives your dataset provider a chance to indicate how records in the delta packet are applied to the database. By default, changes in the delta packet are written to the database using automatically generated SQL UPDATE, INSERT, or DELETE statements such as

Resolving Update Errors On the Provider (see page 1816)	When an error condition arises as the dataset provider tries to post a record in the delta packet, an OnUpdateError event occurs. If the provider can't resolve an update error, it temporarily stores a copy of the offending record. When record processing is complete, the provider returns a count of the errors it encountered, and copies the unresolved records into a results data packet that it passes back to the client for further reconciliation. In multi-tiered applications, this mechanism lets you handle any update errors you can resolve mechanically on the application server, while still allowing user interaction on the... more (see page 1816)
Responding to Client Data Requests (see page 1816)	Usually client requests for data are handled automatically. A client dataset or XML broker requests a data packet by calling GetRecords (indirectly, through the *IAppServer* interface). The provider responds automatically by fetching data from the associated dataset or XML document, creating a data packet, and sending the packet to the client. The provider has the option of editing data after it has been assembled into a data packet but before the packet is sent to the client. For example, you might want to remove records from the packet based on some criterion (such as the user's level of access), or,... more (see page 1816)
Responding to Client-generated Events (see page 1817)	Provider components implement a general-purpose event that lets you create your own calls from client datasets directly to the provider. This is the OnDataRequest event. *OnDataRequest* is not part of the normal functioning of the provider. It is simply a hook to allow your client datasets to communicate directly with providers. The event handler takes an OleVariant as an input parameter and returns an OleVariant. By using OleVariants, the interface is sufficiently general to accommodate almost any information you want to pass to or from the provider. To generate an *OnDataRequest* event, the client application calls the DataRequest method... more (see page 1817)
Screening Individual Updates (see page 1817)	Immediately before each update is applied, a dataset provider receives a BeforeUpdateRecord event. You can use this event to edit records before they are applied, similar to the way you can use the *OnUpdateData* event to edit entire delta packets (see page 1813). For example, the provider does not compare BLOB fields (such as memos) when checking for update conflicts. If you want to check for update errors involving BLOB fields, you can use the *BeforeUpdateRecord* event. In addition, you can use this event to apply updates yourself or to screen and reject updates. The *BeforeUpdateRecord* event handler lets you signal that... more (see page 1817)
Setting Options That Influence the Data Packets (see page 1818)	The Options property of a dataset provider lets you specify when BLOBs or nested detail tables are sent, whether field display properties are included, what type of updates are allowed, and so on. The following table lists the possible values that can be included in *Options*. ***Provider options***
Specifying What Fields Appear in Data Packets (see page 1819)	When using a dataset provider, you can control what fields are included in data packets by creating persistent fields (see page 1859) on the dataset that the provider uses to build data packets. The provider then includes only these fields. Fields whose values are generated dynamically by the source dataset (such as calculated fields or lookup fields) can be included, but appear to client datasets on the receiving end as static read-only fields. If the client dataset will be editing the data and applying updates, you must include enough fields so that there are no duplicate records in the data packet. Otherwise, when... more (see page 1819)
Using Provider Components (see page 1819)	Provider components (TDataSetProvider and TXMLTransformProvider) supply the most common mechanism by which client datasets obtain their data. Providers • Receive data requests from a client dataset (or XML broker), fetch the requested data, package the data into a transportable data packet, and return the data to the client dataset (or XML broker). This activity is called "providing." • Receive updated data from a client dataset (or XML broker), apply updates to the database server, source dataset, or source XML document, and log any updates that cannot be applied, returning unresolved updates to the client dataset for further reconciliation. This activity is... more (see page 1819)

3.2.3.11.1 Responding to Client Update Requests

A provider applies updates to database records based on a *Delta* data packet received from a client dataset or XML broker. The client requests updates by calling the ApplyUpdates method (indirectly, through the *IAppServer* interface).

As with all method calls made through the *IAppServer* interface, the provider can communicate persistent state information (see page 1540) with a client dataset before and after the call to *ApplyUpdates*. This communication takes place using the BeforeApplyUpdates and AfterApplyUpdates event handlers.

If you are using a dataset provider, a number of additional events allow you more control:

When a dataset provider receives an update request, it generates an *OnUpdateData* event, where you can edit the Delta packet (see page 1813) before it is written to the dataset or influence how updates are applied (see page 1815). After the *OnUpdate*Data event, the provider writes the changes to the database or source dataset.

The provider performs the update on a record-by-record basis. Before the dataset provider applies each record, it generates a *BeforeUpdateRecord* event, which you can use to screen updates (see page 1817) before they are applied. If an error occurs when updating a record, the provider receives an *OnUpdateError* event where it can resolve the error (see page 1816). Usually errors occur because the change violates a server constraint or a database record was changed by a different application subsequent to its retrieval by the provider, but prior to the client dataset's request to apply updates.

Update errors can be processed by either the dataset provider or the client dataset. When the provider is part of a multi-tiered application, it should handle all update errors that do not require user interaction to resolve. When the provider can't resolve an error condition, it temporarily stores a copy of the offending record. When record processing is complete, the provider returns a count of the errors it encountered to the client dataset, and copies the unresolved records into a results data packet that it returns to the client dataset for further reconciliation.

The event handlers for all provider events are passed the set of updates as a client dataset. If your event handler is only dealing with certain types of updates, you can filter the dataset based on the update status of records. By filtering the records, your event handler does not need to sort through records it won't be using. To filter the client dataset on the update status of its records, set its StatusFilter property.

Note: Applications must supply extra support when the updates are directed at a dataset that does not represent a single table (see page 1809).

Responding to Client Data Requests (see page 1816)

Choosing How to Apply Updates Using a Dataset Provider (see page 1810)

Determining the Source of Data (see page 1812)

Communicating with the Client Dataset (see page 1811)

3.2.3.11.2 Adding Custom Information to Data Packets

Dataset providers can add application-defined information to data packets using the OnGetDataSetProperties event. This information is encoded as an OleVariant, and stored under a name you specify. Client datasets can then retrieve the information using their GetOptionalParam method. You can also specify that the information be included in delta packets that the client dataset sends when updating records. In this case, the client dataset may never be aware of the information, but the provider

can send a round-trip message to itself.

When adding custom information in the *OnGetDataSetProperties* event, each individual attribute (sometimes called an "optional parameter") is specified using a Variant array that contains three elements: the name (a string), the value (a Variant), and a boolean flag indicating whether the information should be included in delta packets when the client applies updates. Add multiple attributes by creating a Variant array of Variant arrays. For example, the following *OnGetDataSetProperties* event handler sends two values, the time the data was provided and the total number of records in the source dataset. Only the time the data was provided is returned when client datasets apply updates:

```
procedure TMyDataModule1.Provider1GetDataSetProperties(Sender: TObject; DataSet: TDataSet; out
Properties: OleVariant);
begin
  Properties := VarArrayCreate([0,1], varVariant);
  Properties[0] := VarArrayOf(['TimeProvided', Now, True]);
  Properties[1] := VarArrayOf(['TableSize', DataSet.RecordCount, False]);
end;
void __fastcall TMyDataModule1::Provider1GetDataSetProperties(TObject *Sender, TDataSet
*DataSet, out OleVariant Properties)
{
  int ArrayBounds[2];
  ArrayBounds[0] = 0;
  ArrayBounds[1] = 1;
  Properties = VarArrayCreate(ArrayBounds, 1, varVariant);
  Variant values[3];
  values[0] = Variant("TimeProvided");
  values[1] = Variant(Now());
  values[2] = Variant(true);
  Properties[0] = VarArrayOf(values,2);
  values[0] = Variant("TableSize");
  values[1] = Variant(DataSet->RecordCount);
  values[2] = Variant(false);
  Properties[1] = VarArrayOf(values,2);
}
```

When the client dataset applies updates, the time the original records were provided can be read in the provider's OnUpdateData event:

```
procedure TMyDataModule1.Provider1UpdateData(Sender: TObject; DataSet: TCustomClientDataSet);
var
  WhenProvided: TDateTime;
begin
  WhenProvided := DataSet.GetOptionalParam('TimeProvided');
  ...
end;
void __fastcall TMyDataModule1::Provider1UpdateData(TObject *Sender, TCustomClientDataSet
*DataSet)
{
  Variant WhenProvided = DataSet->GetOptionalParam("TimeProvided");
  ...
}
```

Setting Options That Influence the Data Packets (see page 1818)

Adding Application Specific Information to the Data (see page 1709)

3.2.3.11.3 Applying Updates to Datasets That do Not Represent a Single Table

When a dataset provider generates SQL statements that apply updates directly to a database server, it needs the name of the database table that contains the records. This can be handled automatically for many datasets such as table type datasets or

"live" *TQuery* components. Automatic updates are a problem however, if the provider must apply updates to the data underlying a stored procedure with a result set or a multi-table query. There is no easy way to obtain the name of the table to which updates should be applied.

If the query or stored procedure is a BDE-enabled dataset (*TQuery* or *TStoredProc*) and it has an associated update object, the provider uses the update object. However, if there is no update object, you can supply the table name programmatically in an OnGetTableName event handler. Once an event handler supplies the table name, the provider can generate appropriate SQL statements to apply updates.

Supplying a table name only works if the target of the updates is a single database table (that is, only the records in one table need to be updated). If the update requires making changes to multiple underlying database tables, you must explicitly apply the updates in code using the BeforeUpdateRecord event of the provider. Once this event handler has applied an update, you can set the event handler's *Applied* parameter to *True* so that the provider does not generate an error.

Note: If the provider is associated with a BDE-enabled dataset, you can use an update object (see page 1692) in the *BeforeUpdateRecord* event handler to apply updates using customized SQL statements.

Editing Delta Packets Before Updating the Database (see page 1813)

Influencing How Updates Are Applied (see page 1815)

Screening Individual Updates (see page 1817)

3.2.3.11.4 Choosing How to Apply Updates Using a Dataset Provider

TXMLTransformProvider components always apply updates to the associated XML document. When using *TDataSetProvider*, however, you can choose how updates are applied. By default, when *TDataSetProvider* components apply updates and resolve update errors, they communicate directly with the database server using dynamically generated SQL statements. This approach has the advantage that your server application does not need to merge updates twice (first to the dataset, and then to the remote server).

However, you may not always want to take this approach. For example, you may want to use some of the events on the dataset component. Alternately, the dataset you use may not support the use of SQL statements (for example if you are providing from a *TClientDataSet* component.

TDataSetProvider lets you decide whether to apply updates to the database server using SQL or to the source dataset by setting the ResolveToDataSet property. When this property is *True*, updates are applied to the dataset. When it is *False*, updates are applied directly to the underlying database server.

3.2.3.11.5 Communicating with the Client Dataset

All communication between a provider and a client dataset or XML broker takes place through an IAppServer interface. If the provider is in the same application as the client, this interface is implemented by a hidden object generated automatically for you, or by a TLocalConnection component. If the provider is part of a multi-tiered application, this is the interface for the application server's remote data module or (in the case of a SOAP server) an interface generated by the connection component.

Most applications do not use *IAppServer* directly, but invoke it indirectly through the properties and methods of the client dataset or XML broker. However, when necessary, you can make direct calls to the *IAppServer* interface by using the AppServer property of a client dataset.

The following table lists the methods of the *IAppServer* interface, as well as the corresponding methods and events on the provider component and the client dataset. These *IAppServer* methods include a *Provider* parameter. In multi-tiered applications, this parameter indicates the provider on the application server with which the client dataset communicates. Most methods also include an OleVariant parameter called *OwnerData* that allows a client dataset and a provider to pass custom information back and forth. *OwnerData* is not used by default, but is passed to all event handlers so that you can write code that allows your provider to adjust to application-defined information before and after each call from a client dataset.

AppServer interface members

IAppServer	Provider Component	TClientDataSet
AS_ApplyUpdatesAS_ApplyUpdates method	ApplyUpdates method, BeforeApplyUpdates event, AfterApplyUpdates event	ApplyUpdates method, BeforeApplyUpdates event, AfterApplyUpdates event.
AS_DataRequest method	DataRequest method, OnDataRequest event	DataRequest method.
AS_Execute method	Execute method, BeforeExecute event, AfterExecute event	Execute method, BeforeExecute event, AfterExecute event.
AS_GetParams method	GetParams method, BeforeGetParams event, AfterGetParams event	FetchParams method, BeforeGetParams event, AfterGetParams event.
AS_GetProviderNames method	Used to identify all available providers.	Used to create a design-time list for ProviderName property.
AS_GetRecords method	GetRecords method, BeforeGetRecords event, AfterGetRecords event	GetNextPacket method, Data property, BeforeGetRecords event, AfterGetRecords event
AS_RowRequest method	RowRequest method, BeforeRowRequest event, AfterRowRequest event	FetchBlobs method, FetchDetails method, RefreshRecord method, BeforeRowRequest event, AfterRowRequest event

3.2.3.11.6 Controlling What Information Is Included in Data Packets

When working with a dataset provider, there are a number of ways to control what information is included in data packets that are sent to and from the client. These include

- Specifying what fields appear in data packets (see page 1819)
- Setting options that influence the data packets (see page 1818)
- Adding custom information to data packets (see page 1808)

Note: These techniques for controlling the content of data packets are only available for dataset providers. When using *TXMLTransformProvider*, you can only control the content of data packets by controlling the transformation file the provider uses.

Determining the Source of Data (see page 1812)

Communicating with the Client Dataset (see page 1811)

3.2.3.11.7 Determining the Source of Data

When you use a provider component, you must specify the source it uses to get the data it assembles into data packets. Depending on your version of Delphi, you can specify the source as one of the following:

- To provide the data from a dataset, use TDataSetProvider.
- To provide the data from an XML document, use TXMLTransformProvider.

Using a dataset as the source of the data

If the provider is a dataset provider (*TDataSetProvider*), set the DataSet property of the provider to indicate the source dataset. At design time, select from available datasets in the *DataSet* property drop-down list in the **Object Inspector**.

TDataSetProvider interacts with the source dataset using the IProviderSupport interface. This interface is introduced by *TDataSet*, so it is available for all datasets. However, the *IProviderSupport* methods implemented in *TDataSet* are mostly stubs that don't do anything or that raise exceptions.

The dataset classes that ship with Delphi (BDE-enabled datasets, ADO-enabled datasets, *dbExpress* datasets, and InterBase Express datasets) override these methods to implement the *IProviderSupport* interface in a more useful fashion. Client datasets don't add anything to the inherited *IProviderSupport* implementation, but can still be used as a source dataset as long as the *ResolveToDataSet* property of the provider is *True*.

Component writers that create their own custom descendants from *TDataSet* must override all appropriate *IProviderSupport* methods if their datasets are to supply data to a provider. If the provider only provides data packets on a read-only basis (that is, if it does not apply updates), the *IProviderSupport* methods implemented in *TDataSet* may be sufficient.

Using an XML document as the source of the data

If the provider is an XML provider, set the XMLDataFile property of the provider to indicate the source document.

XML providers must transform the source document into data packets, so in addition to indicating the source document, you

must also specify how to transform that document into data packets. This transformation is handled by the provider's TransformRead property. *TransformRead* represents a *TXMLTransform* object. You can set its properties to specify what transformation to use, and use its events to provide your own input to the transformation. For more information on using XML providers, see Using an XML document as the source for a provider (see page 1846).

3.2.3.11.8 Editing Delta Packets Before Updating the Database

Before a dataset provider applies updates to the database, it generates an OnUpdateData event. The *OnUpdateData* event handler receives a copy of the *Delta* packet as a parameter. This is a client dataset.

In the *OnUpdateData* event handler, you can use any of the properties and methods of the client dataset to edit the *Delta* packet before it is written to the dataset. One particularly useful property is the UpdateStatus property. *UpdateStatus* indicates what type of modification the current record in the delta packet represents. It can have any of the values in the following table:

UpdateStatus values

Value	Description
usUnmodified	Record contents have not been changed
usModified	Record contents have been changed
usInserted	Record has been inserted
usDeleted	Record has been deleted

For example, the following *OnUpdateData* event handler inserts the current date into every new record that is inserted into the database:

```
procedure TMyDataModule1.Provider1UpdateData(Sender: TObject; DataSet: TCustomClientDataSet);
begin
  with DataSet do
  begin
    First;
    while not Eof do
    begin
      if UpdateStatus = usInserted then
      begin
        Edit;
        FieldByName('DateCreated').AsDateTime := Date;
        Post;
      end;
      Next;
    end;
end;
void __fastcall TMyDataModule1::Provider1UpdateData(TObject *Sender, TCustomClientDataSet
*DataSet)
{
```

```
    DataSet->First();
    while (!DataSet->Eof)
    {
      if (DataSet->UpdateStatus == usInserted)
      {
        DataSet->Edit();
        DataSet->FieldByName("DateCreated")->AsDateTime = Date();
        DataSet->Post();
      }
      DataSet->Next();
    }
  }
```

3.2.3.11.9 Handling Server Constraints

Most relational database management systems implement constraints on their tables to enforce data integrity. A constraint is a rule that governs data values in tables and columns, or that governs data relationships across columns in different tables. For example, most SQL-92 compliant relational databases support the following constraints:

- NOT NULL, to guarantee that a value supplied to a column has a value.
- NOT NULL UNIQUE, to guarantee that column value has a value and does not duplicate any other value already in that column for another record.
- CHECK, to guarantee that a value supplied to a column falls within a certain range, or is one of a limited number of possible values.
- CONSTRAINT, a table-wide check constraint that applies to multiple columns.
- PRIMARY KEY, to designate one or more columns as the table's primary key for indexing purposes.
- FOREIGN KEY, to designate one or more columns in a table that reference another table.

Note: This list is not exclusive. Your database server may support some or all of these constraints in part or in whole, and may support additional constraints. For more information about supported constraints, see your server documentation.

Database server constraints obviously duplicate many kinds of data checks that traditional desktop database applications manage. You can take advantage of server constraints in multi-tiered database applications without having to duplicate the constraints in application server or client application code.

If the provider is working with a BDE-enabled dataset, the *Constraints* property lets you replicate and apply server constraints to data passed to and received from client datasets. When *Constraints* is *True* (the default), server constraints stored in the source dataset are included in data packets and affect client attempts to update data.

Warning: Before the provider can pass constraint information on to client datasets, it must retrieve the constraints from the database server.

There may be times when you do not want to apply server constraints to data sent to a client dataset. For example, a client dataset that receives data in packets and permits local updating of records prior to fetching more records may need to disable some server constraints that might be triggered because of the temporarily incomplete set of data. To prevent constraint replication from the provider to a client dataset, set *Constraints* to *False*. Note that client datasets can disable and enable constraints using the *DisableConstraints* and *EnableConstraints* methods. For more information about enabling and disabling constraints from the client dataset, see Handling constraints from the server (see page 1716).

Communicating with the Client Dataset (see page 1811)

3.2.3.11.10 Influencing How Updates Are Applied

The OnUpdateData event gives your dataset provider a chance to indicate how records in the delta packet are applied to the database.

By default, changes in the delta packet are written to the database using automatically generated SQL UPDATE, INSERT, or DELETE statements such as

```
UPDATE EMPLOYEES
set EMPNO = 748, NAME = 'Smith', TITLE = 'Programmer 1', DEPT = 52
WHERE
EMPNO = 748 and NAME = 'Smith' and TITLE = 'Programmer 1' and DEPT = 47
```

Unless you specify otherwise, all fields in the delta packet records are included in the UPDATE clause and in the WHERE clause. However, you may want to exclude some of these fields. One way to do this is to set the UpdateMode property of the provider. *UpdateMode* can be assigned any of the following values:

UpdateMode values

Value	Meaning
upWhereAll	All fields are used to locate fields (the WHERE clause).
upWhereChanged	Only key fields and fields that are changed are used to locate records.
upWhereKeyOnly	Only key fields are used to locate records.

You might, however, want even more control. For example, with the previous statement, you might want to prevent the EMPNO field from being modified by leaving it out of the UPDATE clause and leave the TITLE and DEPT fields out of the WHERE clause to avoid update conflicts when other applications have modified the data. To specify the clauses where a specific field appears, use the ProviderFlags property. *ProviderFlags* is a set that can include any of the values in the following table

ProviderFlags values

Value	Description
pfInWhere	The field appears in the WHERE clause of generated INSERT, DELETE, and UPDATE statements when *UpdateMode* is *upWhereAll* or *upWhereChanged*.
pfInUpdate	The field appears in the UPDATE clause of generated UPDATE statements.
pfInKey	The field is used in the WHERE clause of generated statements when *UpdateMode* is *upWhereKeyOnly*.
pfHidden	The field is included in records to ensure uniqueness, but can't be seen or used on the client side.

Thus, the following *OnUpdateData* event handler allows the TITLE field to be updated and uses the EMPNO and DEPT fields to locate the desired record. If an error occurs, and a second attempt is made to locate the record based only on the key, the generated SQL looks for the EMPNO field only:

```
procedure TMyDataModule1.Provider1UpdateData(Sender: TObject; DataSet: TCustomClientDataSet);
begin
```

```
  with DataSet do
  begin
    FieldByName('TITLE').ProviderFlags := [pfInUpdate];
    FieldByName('EMPNO').ProviderFlags := [pfInWhere, pfInKey];
    FieldByName('DEPT').ProviderFlags := [pfInWhere];
  end;
end;
void __fastcall TMyDataModule1::Provider1UpdateData(TObject *Sender, TCustomClientDataSet
*DataSet)
{
  DataSet->FieldByName("EMPNO")->ProviderFlags.Clear();
  DataSet->FieldByName("EMPNO")->ProviderFlags << pfInWHere << pfInKey;
  DataSet->FieldByName("TITLE")->ProviderFlags.Clear();
  DataSet->FieldByName("TITLE")->ProviderFlags << pfInUpdate;
  DataSet->FieldByName("DEPT")->ProviderFlags.Clear();
  DataSet->FieldByName("DEPT")->ProviderFlags << pfInWhere;
}
```

Note: You can use the *UpdateFlags* property to influence how updates are applied even if you are updating to a dataset and not using dynamically generated SQL. These flags still determine which fields are used to locate records and which fields get updated.

3.2.3.11.11 Resolving Update Errors On the Provider

When an error condition arises as the dataset provider tries to post a record in the delta packet, an OnUpdateError event occurs. If the provider can't resolve an update error, it temporarily stores a copy of the offending record. When record processing is complete, the provider returns a count of the errors it encountered, and copies the unresolved records into a results data packet that it passes back to the client for further reconciliation.

In multi-tiered applications, this mechanism lets you handle any update errors you can resolve mechanically on the application server, while still allowing user interaction on the client application to correct error conditions.

The *OnUpdateError* handler gets a copy of the record that could not be changed, an error code from the database, and an indication of whether the resolver was trying to insert, delete, or update the record. The problem record is passed back in a client dataset. You should never use the data navigation methods on this dataset. However, for each field in the dataset, you can use the NewValue, OldValue, and CurValue properties to determine the cause of the problem and make any modifications to resolve the update error. If the *OnUpdateError* event handler can correct the problem, it sets the *Response* parameter so that the corrected record is applied.

3.2.3.11.12 Responding to Client Data Requests

Usually client requests for data are handled automatically. A client dataset or XML broker requests a data packet by calling GetRecords (indirectly, through the *IAppServer* interface). The provider responds automatically by fetching data from the

associated dataset or XML document, creating a data packet, and sending the packet to the client.

The provider has the option of editing data after it has been assembled into a data packet but before the packet is sent to the client. For example, you might want to remove records from the packet based on some criterion (such as the user's level of access), or, in a multi-tiered application, you might want to encrypt sensitive data before it is sent on to the client.

To edit the data packet before sending it on to the client, write an OnGetData event handler. *OnGetData* event handlers provide the data packet as a parameter in the form of a client dataset. Using the methods of this client dataset, you can edit data before it is sent to the client.

As with all method calls made through the *IAppServer* interface, the provider can communicate persistent state information (see page 1540) with a client dataset before and after the call to *GetRecords*. This communication takes place using the BeforeGetRecords and AfterGetRecords event handlers.

Communicating with the Client Dataset (see page 1811)

3.2.3.11.13 Responding to Client-generated Events

Provider components implement a general-purpose event that lets you create your own calls from client datasets directly to the provider. This is the OnDataRequest event.

OnDataRequest is not part of the normal functioning of the provider. It is simply a hook to allow your client datasets to communicate directly with providers. The event handler takes an OleVariant as an input parameter and returns an OleVariant. By using OleVariants, the interface is sufficiently general to accommodate almost any information you want to pass to or from the provider.

To generate an *OnDataRequest* event, the client application calls the DataRequest method of the client dataset.

Choosing How to Apply Updates Using a Dataset Provider (see page 1810)

Determining the Source of Data (see page 1812)

Communicating with the Client Dataset (see page 1811)

3.2.3.11.14 Screening Individual Updates

Immediately before each update is applied, a dataset provider receives a BeforeUpdateRecord event. You can use this event to

edit records before they are applied, similar to the way you can use the *OnUpdateData* event to edit entire delta packets (see page 1813). For example, the provider does not compare BLOB fields (such as memos) when checking for update conflicts. If you want to check for update errors involving BLOB fields, you can use the *BeforeUpdateRecord* event.

In addition, you can use this event to apply updates yourself or to screen and reject updates. The *BeforeUpdateRecord* event handler lets you signal that an update has been handled already and should not be applied. The provider then skips that record, but does not count it as an update error. For example, this event provides a mechanism for applying updates to a stored procedure (which can't be updated automatically), allowing the provider to skip any automatic processing once the record is updated from within the event handler.

Editing Delta Packets Before Updating the Database (see page 1813)

Influencing How Updates Are Applied (see page 1815)

Applying Updates to Datasets That do Not Represent a Single Table (see page 1809)

3.2.3.11.15 Setting Options That Influence the Data Packets

The Options property of a dataset provider lets you specify when BLOBs or nested detail tables are sent, whether field display properties are included, what type of updates are allowed, and so on. The following table lists the possible values that can be included in *Options*.

Provider options

Value	Meaning
poAutoRefresh	The provider refreshes the client dataset with current record values whenever it applies updates.
poReadOnly	The client dataset can't apply updates to the provider.
poDisableEdits	Client datasets can't modify existing data values. If the user tries to edit a field, the client dataset raises exception. (This does not affect the client dataset's ability to insert or delete records).
poDisableInserts	Client datasets can't insert new records. If the user tries to insert a new record, the client dataset raises an exception. (This does not affect the client dataset's ability to delete records or modify existing data)
poDisableDeletes	Client datasets can't delete records. If the user tries to delete a record, the client dataset raises an exception. (This does not affect the client dataset's ability to insert or modify records)
poFetchBlobsOnDemand	BLOB field values are not included in data packets. Instead, client datasets must request these values on an as-needed basis. If the client dataset's *FetchOnDemand* property is *True*, it requests these values automatically. Otherwise, the application must call the client dataset's *FetchBlobs* method to retrieve BLOB data.
poFetchDetailsOnDemand	When the provider's dataset represents the master of a master/detail relationship, nested detail values are not included in data packets. Instead, client datasets request these on an as-needed basis. If the client dataset's *FetchOnDemand* property is *True*, it requests these values automatically. Otherwise, the application must call the client dataset's *FetchDetails* method to retrieve nested details.
poIncFieldProps	The data packet includes the following field properties (where applicable): *Alignment*, *DisplayLabel*, *DisplayWidth*, *Visible*, *DisplayFormat*, *EditFormat*, *MaxValue*, *MinValue*, *Currency*, *EditMask*, *DisplayValues.*
poCascadeDeletes	When the provider's dataset represents the master of a master/detail relationship, the server automatically deletes detail records when master records are deleted. To use this option, the database server must be set up to perform cascaded deletes as part of its referential integrity.

poCascadeUpdates	When the provider's dataset represents the master of a master/detail relationship, key values on detail tables are updated automatically when the corresponding values are changed in master records. To use this option, the database server must be set up to perform cascaded updates as part of its referential integrity.
poAllowMultiRecordUpdates	A single update can cause more than one record of the underlying database table to change. This can be the result of triggers, referential integrity, SQL statements on the source dataset, and so on. Note that if an error occurs, the event handlers provide access to the record that was updated, not the other records that change in consequence.
poNoReset	Client datasets can't specify that the provider should reposition the cursor on the first record before providing data.
poPropogateChanges	Changes made by the server to updated records as part of the update process are sent back to the client and merged into the client dataset.
poAllowCommandText	The client can override the associated dataset's SQL text or the name of the table or stored procedure it represents.
poRetainServerOrder	The client dataset should not re-sort the records in the dataset to enforce a default order.

Specifying What Fields Appear in Data Packets (see page 1819)

Adding Custom Information to Data Packets (see page 1808)

3.2.3.11.16 Specifying What Fields Appear in Data Packets

When using a dataset provider, you can control what fields are included in data packets by creating persistent fields (see page 1859) on the dataset that the provider uses to build data packets. The provider then includes only these fields. Fields whose values are generated dynamically by the source dataset (such as calculated fields or lookup fields) can be included, but appear to client datasets on the receiving end as static read-only fields.

If the client dataset will be editing the data and applying updates, you must include enough fields so that there are no duplicate records in the data packet. Otherwise, when the updates are applied, it is impossible to determine which record to update. If you do not want the client dataset to be able to see or use extra fields provided only to ensure uniqueness, set the ProviderFlags property for those fields to include *pfHidden*.

Note: Including enough fields to avoid duplicate records is also a consideration when the provider's source dataset represents a query. You must specify the query so that it includes enough fields to ensure all records are unique, even if your application does not use all the fields.

Setting Options That Influence the Data Packets (see page 1818)

Adding Custom Information to Data Packets (see page 1808)

Persistent Field Components (see page 1859)

3.2.3.11.17 Using Provider Components

Provider components (TDataSetProvider and TXMLTransformProvider) supply the most common mechanism by which client datasets obtain their data. Providers

- Receive data requests from a client dataset (or XML broker), fetch the requested data, package the data into a transportable data packet, and return the data to the client dataset (or XML broker). This activity is called "providing."
- Receive updated data from a client dataset (or XML broker), apply updates to the database server, source dataset, or source

XML document, and log any updates that cannot be applied, returning unresolved updates to the client dataset for further reconciliation. This activity is called "resolving."

Most of the work of a provider component happens automatically. You need not write any code on the provider to create data packets from the data in a dataset or XML document or to apply updates. However, provider components include a number of events and properties that allow your application more direct control over what information is packaged for clients and how your application responds to client requests.

When using *TBDEClientDataSet*, *TSimpleDataSet*, or *TIBClientDataSet*, the provider is internal to the client dataset, and the application has no direct access to it. When using *TClientDataSet* or *TXMLBroker*, however, the provider is a separate component that you can use to control what information is packaged for clients and for responding to events that occur around the process of providing and resolving. The client datasets that have internal providers surface some of the internal provider's properties and events as their own properties and events, but for the greatest amount of control, you may want to use *TClientDataSet* with a separate provider component.

When using a separate provider component, it can reside in the same application as the client dataset (or XML broker), or it can reside on an application server as part of a multi-tiered application.

The following topics describe how to use a provider component to control the interaction with client datasets or XML brokers.

- Determining the Source of Data (see page 1812)
- Communicating with the Client Dataset (see page 1811)
- Choosing How to Apply Updates Using a Dataset Provider (see page 1810)
- Controlling what Information is Included in Data Packets (see page 1812)
- Responding to Client Data Requests (see page 1816)
- Responding to Client Update Requests (see page 1808)
- Responding to Client-generated Events (see page 1817)
- Handling Server Constraints (see page 1814)

3.2.3.12 Using dbExpress Components

Topics

Name	Description
Using dbExpress Datasets (see page 1823)	*dbExpress* is a set of lightweight database drivers that provide fast access to SQL database servers. For each supported database, *dbExpress* provides a driver that adapts the server-specific software to a set of uniform *dbExpress* interfaces. When you deploy a database application that uses *dbExpress*, you need only include a dll (the server-specific driver) with the application files you build. *dbExpress* lets you access databases using unidirectional datasets. Unidirectional datasets are designed for quick lightweight access to database information, with minimal overhead. Like other datasets, they can send an SQL command to the database server, and if the command... more (see page 1823)
Accessing dbExpress Schema Information (see page 1824)	There are two ways to obtain information about what is available on the server. This information, called schema information or metadata, includes information about what tables and stored procedures are available on the server and information about these tables and stored procedures (such as the fields a table contains, the indexes that are defined, and the parameters a stored procedure uses). The simplest way to obtain this metadata is to use the methods of TSQLConnection. These methods fill an existing string list or list object with the names of tables, stored procedures, fields, or indexes, or with parameter descriptors. This... more (see page 1824)
Connecting to the Database Server (see page 1825)	The first step when working with a dbExpress dataset is to connect it to a database server. At design time, once a dataset has an active connection to a database server, the **Object Inspector** can provide drop-down lists of values for other properties. For example, when representing a stored procedure, you must have an active connection before the **Object Inspector** can list what stored procedures are available on the server. The connection to a database server is represented by a separate TSQLConnection component. You work with *TSQLConnection* like any other database connection component (see page 1506). To use *TSQLConnection* to connect a... more (see page 1825)
Creating and Modifying Server Metadata (see page 1826)	Most of the commands that do not return data fall into two categories: those that you use to edit data (such as INSERT, DELETE, and UPDATE commands), and those that you use to create or modify entities on the server such as tables, indexes, and stored procedures. If you don't want to use explicit SQL commands for editing, you can link your unidirectional dataset to a client dataset (see page 1559) and let it handle all the generation of all SQL commands concerned with editing. In fact, this is the recommended approach because data-aware controls are designed to perform edits through a dataset... more (see page 1826)
Debugging dbExpress Applications (see page 1827)	While you are debugging your database application, it may prove useful to monitor the SQL messages that are sent to and from the database server through your connection component, including those that are generated automatically for you (for example by a provider component or by the *dbExpress* driver).
Executing Commands That Do Not Return Records (see page 1829)	You can use a dbExpress dataset even if the query or stored procedure it represents does not return any records. Such commands include statements that use Data Definition Language (DDL) or Data Manipulation Language (DML) statements other than SELECT statements (For example, INSERT, DELETE, UPDATE, CREATE INDEX, and ALTER TABLE commands do not return any records). The language used in commands is server-specific, but usually compliant with the SQL-92 standard for the SQL language. The SQL command you execute must be acceptable to the server you are using. Unidirectional datasets neither evaluate the SQL nor execute it. They merely pass... more (see page 1829)
Executing the Command (see page 1829)	To execute a query or stored procedure that does not return any records, you do not use the *Active* property or the *Open* method. Instead, you must use The ExecSQL method if the dataset is an instance of *TSQLDataSet* or *TSQLQuery*.

Fetching Metadata into a dbExpress Dataset (see page 1830)	To populate a unidirectional dataset with metadata from the database server, you must first indicate what data you want to see, using the SetSchemaInfo method. *SetSchemaInfo* takes three parameters: • The type of schema information (metadata) you want to fetch. This can be a list of tables (*stTables*), a list of system tables (*stSysTables*), a list of stored procedures (*stProcedures*), a list of fields in a table (*stColumns*), a list of indexes (*stIndexes*), or a list of parameters used by a stored procedure (*stProcedureParams*). Each type of information uses... more (see page 1830)
Fetching the Data (see page 1830)	Once you have specified the source of the data (see page 1836), you must fetch the data before your application can access it. Once the dataset has fetched the data, data-aware controls linked to the dataset through a data source automatically display data values and client datasets linked to the dataset through a provider can be populated with records. As with any dataset, there are two ways to fetch the data for a dbExpress dataset: One way is to set the Active*property to True, either at design time in the* ***Object Inspector****, or in code at runtime:*
Representing the Records in a Table (see page 1832)	When you want to represent all of the fields and all of the records in a single underlying database table, you can use either *TSQLDataSet* or *TSQLTable* to generate the query for you rather than writing the SQL yourself. **Note:** If server performance is a concern, you may want to compose the query explicitly rather than relying on an automatically-generated query. Automatically-generated queries use wildcards rather than explicitly listing all of the fields in the table. This can result in slightly slower performance on the server. The wildcard (*) in automatically-generated queries is more robust to changes in the fields... more (see page 1832)
Representing the Results of a Query (see page 1832)	Using a query is the most general way to specify a set of records. Queries are simply commands written in SQL. You can use either *TSQLDataSet* or *TSQLQuery* to represent the result of a query. When using *TSQLDataSet*, set the CommandType property to *ctQuery* and assign the text of the query statement to the CommandText property. When using *TSQLQuery*, assign the query to the SQL property instead. These properties work the same way for all general-purpose or query-type datasets. Specifying the query (see page 1613) discusses them in greater detail. When you specify the query, it can include parameters, or variables,... more (see page 1832)
Representing the Results of a Stored Procedure (see page 1833)	Stored procedures are sets of SQL statements that are named and stored on an SQL server. How you indicate the stored procedure you want to execute depends on the type of unidirectional dataset you are using. When using TSQLDataSet, to specify a stored procedure: • Set the CommandType property to *ctStoredProc*. • Specify the name of the stored procedure as the value of the CommandText property:
Setting Up Master/Detail Linked Relationships (see page 1833)	There are two ways to use linked datasets to set up a master/detail relationship with a dbExpress dataset as the detail set. Which method you use depends on the type of unidirectional dataset (see page 1836) you are using. Once you have set up such a relationship, the unidirectional dataset (the "many" in a one-to-many relationship) provides access only to those records that correspond to the current record on the master set (the "one" in the one-to-many relationship). *TSQLDataSet* and *TSQLQuery* require you to use a parameterized query to establish a master/detail relationship. This is the technique for creating such relationships on all... more (see page 1833)
Setting Up TSQLConnection (see page 1834)	In order to describe a database connection in sufficient detail for TSQLConnection to open a connection, you must identify both the driver to use and a set of connection parameters the are passed to that driver.

Specifying the Command to Execute (see page 1835)	With unidirectional datasets, the way you specify the command to execute is the same whether the command results in a dataset or not. That is: When using TSQLDataSet, use the CommandType and CommandText properties to specify the command: • If *CommandType* is *ctQuery*, *CommandText* is the SQL statement to pass to the server. • If *CommandType* is *ctStoredProc*, *CommandText* is the name of a stored procedure to execute. When using TSQLQuery, use the SQL property to specify the SQL statement to pass to the server. When using TSQLStoredProc, use the StoredProcName property to specify the name of the stored procedure... more (see page 1835)
Specifying What Data to Display (see page 1836)	There are a number of ways to specify what data a dbExpress dataset represents. Which method you choose depends on the type of unidirectional dataset (see page 1836) you are using and whether the information comes from a single database table, the results of a query, or from a stored procedure. When you work with a TSQLDataSet component, use the CommandType property to indicate where the dataset gets its data. *CommandType* can take any of the following values: • *ctQuery*: When *CommandType* is *ctQuery*, *TSQLDataSet* executes a query you specify. If the query is a SELECT command, the dataset contains the resulting... more (see page 1836)
Types of dbExpress Datasets (see page 1836)	The *dbExpress* category of the **Tool palette** contains four types of unidirectional dataset: TSQLDataSet, TSQLQuery, TSQLTable, and TSQLStoredProc. *TSQLDataSet* is the most general of the four. You can use an SQL dataset to represent any data available through *dbExpress*, or to send commands to a database accessed through *dbExpress*. This is the recommended component to use for working with database tables in new database applications. *TSQLQuery* is a query-type dataset (see page 1618) that encapsulates an SQL statement and enables applications to access the resulting records, if any. *TSQLTable* is a table-type dataset (see page 1620) that represents all of the rows and columns... more (see page 1836)
The Structure of Metadata Datasets (see page 1837)	For each type of metadata you can access using *TSQLDataSet*, there is a predefined set of columns (fields) that are populated with information about the items of the requested type.

3.2.3.12.1 Using dbExpress Datasets

dbExpress is a set of lightweight database drivers that provide fast access to SQL database servers. For each supported database, *dbExpress* provides a driver that adapts the server-specific software to a set of uniform *dbExpress* interfaces. When you deploy a database application that uses *dbExpress*, you need only include a dll (the server-specific driver) with the application files you build.

dbExpress lets you access databases using unidirectional datasets. Unidirectional datasets are designed for quick lightweight access to database information, with minimal overhead. Like other datasets, they can send an SQL command to the database server, and if the command returns a set of records, obtain a cursor for accessing those records. However, unidirectional datasets can only retrieve a unidirectional cursor. They do not buffer data in memory, which makes them faster and less resource-intensive than other types of dataset. However, because there are no buffered records, unidirectional datasets are also less flexible than other datasets. Many of the capabilities introduced by TDataSet (see page 1632) are either unimplemented in unidirectional datasets, or cause them to raise exceptions. For example:

- The only supported navigation methods are the First and Next methods. Most others raise exceptions. Some, such as the methods involved in bookmark support, simply do nothing.
- There is no built-in support for editing because editing requires a buffer to hold the edits. The CanModify property is always *False*, so attempts to put the dataset into edit mode always fail. You can, however, use unidirectional datasets to update data

using an SQL UPDATE command or provide conventional editing support by using a dbExpress-enabled client dataset or connecting the dataset to a client dataset (see page 1561) .

- There is no support for filters, because filters work with multiple records, which requires buffering. If you try to filter a unidirectional dataset, it raises an exception. Instead, all limits on what data appears must be imposed using the SQL command that defines the data for the dataset.
- There is no support for lookup fields, which require buffering to hold multiple records containing lookup values. If you define a lookup field on a unidirectional dataset, it does not work properly.

Despite these limitations, unidirectional datasets are a powerful way to access data. They are the fastest data access mechanism, and very simple to use and deploy.

The following topics describe unidirectional datasets in greater detail:

- Types of dbExpress datasets (see page 1836)
- Connecting to the database server (see page 1825)
- Specifying what data to display (see page 1836)
- Fetching the data (see page 1830)
- Executing commands that do not return records (see page 1829)
- Setting up master/detail linked cursors (see page 1833)
- Accessing Schema Information (see page 1824)
- Debugging dbExpress applications (see page 1827)

3.2.3.12.2 Accessing dbExpress Schema Information

There are two ways to obtain information about what is available on the server. This information, called schema information or metadata, includes information about what tables and stored procedures are available on the server and information about these tables and stored procedures (such as the fields a table contains, the indexes that are defined, and the parameters a stored procedure uses).

The simplest way to obtain this metadata is to use the methods of TSQLConnection. These methods fill an existing string list or list object with the names of tables, stored procedures, fields, or indexes, or with parameter descriptors. This technique is the same as the way you fill lists with metadata for any other database connection component. These methods are described in Obtaining metadata (see page 1501).

If you require more detailed schema information, you can populate a unidirectional dataset with metadata. Instead of a simple list, the unidirectional dataset is filled with schema information, where each record represents a single table, stored procedure, index, field, or parameter. See Fetching metadata into a unidirectional dataset (see page 1830) for details on populating a unidirectional dataset with schema information.

3.2.3.12.3 Connecting to the Database Server

The first step when working with a dbExpress dataset is to connect it to a database server. At design time, once a dataset has an active connection to a database server, the **Object Inspector** can provide drop-down lists of values for other properties. For example, when representing a stored procedure, you must have an active connection before the **Object Inspector** can list what stored procedures are available on the server.

The connection to a database server is represented by a separate TSQLConnection component. You work with *TSQLConnection* like any other database connection component (see page 1506).

To use *TSQLConnection* to connect a unidirectional dataset to a database server, set the SQLConnection property. At design time, you can choose the SQL connection component from a drop-down list in the **Object Inspector**. If you make this assignment at runtime, be sure that the connection is active:

```
SQLDataSet1.SQLConnection := SQLConnection1;
SQLConnection1.Connected := True;
SQLDataSet1->SQLConnection = SQLConnection1;
SQLConnection1->Connected = true;
```

Typically, all unidirectional datasets in an application share the same connection component, unless you are working with data from multiple database servers. However, you may want to use a separate connection for each dataset if the server does not support multiple statements per connection. Check whether the database server requires a separate connection for each dataset by reading the MaxStmtsPerConn property. By default, *TSQLConnection* generates connections as needed when the server limits the number of statements that can be executed over a connection. If you want to keep stricter track of the connections you are using, set the AutoClone property to *False*.

Before you assign the *SQLConnection* property, you will need to set up the TSQLConnection component (see page 1834) so that it identifies the database server and any required connection parameters (including which database to use on the server, the host name of the machine running the server, the username, password, and so on).

3.2.3.12.4 Creating and Modifying Server Metadata

Most of the commands that do not return data fall into two categories: those that you use to edit data (such as INSERT, DELETE, and UPDATE commands), and those that you use to create or modify entities on the server such as tables, indexes, and stored procedures.

If you don't want to use explicit SQL commands for editing, you can link your unidirectional dataset to a client dataset (see page 1559) and let it handle all the generation of all SQL commands concerned with editing. In fact, this is the recommended approach because data-aware controls are designed to perform edits through a dataset such as *TClientDataSet*.

The only way your application can create or modify metadata on the server, however, is to send a command. Not all database drivers support the same SQL syntax. It is beyond the scope of this topic to describe the SQL syntax supported by each database type and the differences between the database types. For a comprehensive and up-to-date discussion of the SQL implementation for a given database system, see the documentation that comes with that system.

In general, use the CREATE TABLE statement to create tables in a database and CREATE INDEX to create new indexes for those tables. Where supported, use other CREATE statements for adding various metadata objects, such as CREATE DOMAIN, CREATE VIEW, CREATE SCHEMA, and CREATE PROCEDURE.

For each of the CREATE statements, there is a corresponding DROP statement to delete the metadata object. These statements include DROP TABLE, DROP VIEW, DROP DOMAIN, DROP SCHEMA, and DROP PROCEDURE.

To change the structure of a table, use the ALTER TABLE statement. ALTER TABLE has ADD and DROP clauses to create new elements in a table and to delete them. For example, use the ADD COLUMN clause to add a new column to the table and DROP CONSTRAINT to delete an existing constraint from the table.

For example, the following statement creates a stored procedure called GET_EMP_PROJ on an InterBase database:

```
CREATE PROCEDURE GET_EMP_PROJ (EMP_NO SMALLINT)
RETURNS (PROJ_ID CHAR(5))
AS
BEGIN
  FOR SELECT PROJ_ID
  FROM EMPLOYEE_PROJECT
  WHERE EMP_NO = :EMP_NO
  INTO :PROJ_ID
  DO
    SUSPEND;
END
```

The following code uses a *TSQLDataSet* to create this stored procedure. Note the use of the *ParamCheck* property to prevent the dataset from confusing the parameters in the stored procedure definition (:EMP_NO and :PROJ_ID) with a parameter of the query that creates the stored procedure.

```
with SQLDataSet1 do
begin
  ParamCheck := False;
  CommandType := ctQuery;
  CommandText := 'CREATE PROCEDURE GET_EMP_PROJ (EMP_NO SMALLINT) ' +
      'RETURNS (PROJ_ID CHAR(5)) AS ' +
      'BEGIN ' +
        'FOR SELECT PROJ_ID FROM EMPLOYEE_PROJECT ' +
        'WHERE EMP_NO = :EMP_NO ' +
        'INTO :PROJ_ID ' +
          'DO SUSPEND; ' +
```

```
        END';
    ExecSQL;
end;
SQLDataSet1->ParamCheck = false;
SQLDataSet1->CommandType = ctQuery;
SQLDataSet1->CommandText = "CREATE PROCEDURE GET_EMP_PROJ (EMP_NO SMALLINT) RETURNS (PROJ_ID
CHAR(5)) AS BEGIN FOR SELECT PROJ_ID FROM EMPLOYEE_PROJECT WHERE EMP_NO = :EMP_NO INTO
:PROJ_ID DO SUSPEND; END";
SQLDataSet1->ExecSQL();
```

3.2.3.12.5 Debugging dbExpress Applications

While you are debugging your database application, it may prove useful to monitor the SQL messages that are sent to and from the database server through your connection component, including those that are generated automatically for you (for example by a provider component or by the *dbExpress* driver).

Using TSQLMonitor to monitor SQL commands

TSQLConnection uses a companion component, TSQLMonitor, to intercept these messages and save them in a string list. *TSQLMonitor* works much like the SQL monitor utility that you can use with the BDE, except that it monitors only those commands involving a single *TSQLConnection* component rather than all commands managed by *dbExpress*.

To use TSQLMonitor

1. Add a *TSQLMonitor* component to the form or data module containing the *TSQLConnection* component whose SQL commands you want to monitor.
2. Set its SQLConnection property to the *TSQLConnection* component.
3. Set the SQL monitor's Active property to *True*.

Flags for monitoring SQL commands

Flag	Meaning
traceUNKNOWN	All SQL commands.
traceQPREPARE	prepared queries sent to the server.
traceQEXECUTE	Queries to be executed by the server. Note that a single statement may be prepared once and executed several times with different parameter bindings.
traceERROR	Error messages returned by the server. The error message may include an error code, depending on the server.
traceSTMT	Operations to be performed such as ALLOCATE, PREPARE, EXECUTE, and FETCH.
traceCONNECT	Operations associated with connecting and disconnecting to databases, including allocation of connection handles and freeing connection handles, if required by server.
traceTRANSACT	Transaction operations such as BEGIN, COMMIT, and ROLLBACK (ABORT).
traceBLOB	Operations on Binary Large Object (BLOB) data, including STORE BLOB, GET BLOB HANDLE, and so on.
traceMISC	commands not covered by any other flag.
traceVENDOR	API function calls to the server. For example, ORLON for Oracle, ISC_ATTACH for InterBase.
traceDATAIN	Parameter data sent to servers when doing INSERTs or UPDATEs.
traceDATAOUT	Data retrieved from servers.

As SQL commands are sent to the server, the SQL monitor's TraceList property is automatically updated to list all the SQL commands that are intercepted.

You can save this list to a file by specifying a value for the FileName property and then setting the AutoSave property to *True*. *AutoSave* causes the SQL monitor to save the contents of the *TraceList* property to a file every time is logs a new message.

If you do not want the overhead of saving a file every time a message is logged, you can use the OnLogTrace event handler to only save files after a number of messages have been logged. For example, the following event handler saves the contents of *TraceList* every 10th message, clearing the log after saving it so that the list never gets too long:

```
procedure TForm1.SQLMonitor1LogTrace(Sender: TObject; CBInfo: Pointer);
var
  LogFileName: string;
begin
  with Sender as TSQLMonitor do
  begin
    if TraceCount = 10 then
    begin
      LogFileName := 'c:\log' + IntToStr(Tag) + '.txt';
      Tag := Tag + 1; {ensure next log file has a different name }
      SaveToFile(LogFileName);
      TraceList.Clear; { clear list }
    end;
  end;
end;
void __fastcall TForm1::SQLMonitor1LogTrace(TObject *Sender, void *CBInfo)
{
  TSQLMonitor *pMonitor = dynamic_cast<TSQLMonitor *>(Sender);
  if (pMonitor->TraceCount == 10)
  {
    // build unique file name
    AnsiString LogFileName = "c:\\log";
    LogFileName = LogFileName + IntToStr(pMonitor->Tag);
    LogFileName = LogFileName + ".txt"
    pMonitor->Tag = pMonitor->Tag + 1;
    // Save contents of log and clear the list
    pMonitor->SaveToFile(LogFileName);
    pMonitor->TraceList->Clear();

}
```

Note: If you were to use the previous event handler, you would also want to save any partial list (fewer than 10 entries) when the application shuts down.

Using a callback to monitor SQL commands

Instead of using *TSQLMonitor*, you can customize the way your application traces SQL commands by using the SQL connection component's SetTraceEvent method. *SetTraceEvent* takes a TDBXTraceEvent parameter .

The *dbExpress* driver triggers the event every time the SQL connection component passes a command to the server or the server returns an error message.

Warning: Do not call *SetTraceEvent* if the *TSQLConnection* object has an associated *TSQLMonitor* component. *TSQLMonitor* uses the callback mechanism to work, and *TSQLConnection* can only support one callback at a time.

3.2.3.12.6 Executing Commands That Do Not Return Records

You can use a dbExpress dataset even if the query or stored procedure it represents does not return any records. Such commands include statements that use Data Definition Language (DDL) or Data Manipulation Language (DML) statements other than SELECT statements (For example, INSERT, DELETE, UPDATE, CREATE INDEX, and ALTER TABLE commands do not return any records). The language used in commands is server-specific, but usually compliant with the SQL-92 standard for the SQL language.

The SQL command you execute must be acceptable to the server you are using. Unidirectional datasets neither evaluate the SQL nor execute it. They merely pass the command to the server for execution.

Note: If the command does not return any records, you do not need to use a unidirectional dataset at all, because there is no need for the dataset methods that provide access to a set of records. The SQL connection component that connects to the database server can be used directly to execute a command on the server. See Sending commands to the server (see page 1502) for details.

The following topics discuss how to create and execute a command that does not return any records:

- Specifying the command to execute (see page 1835)
- Executing the command (see page 1829)

In addition, the topic,Creating and modifying server metadata (see page 1826), discusses some of the SQL commands that do not return datasets:

Accessing Schema Information (see page 51)

Fetching the Data (see page 1830)

Debugging dbExpress Applications (see page 55)

3.2.3.12.7 Executing the Command

To execute a query or stored procedure that does not return any records, you do not use the *Active* property or the *Open* method. Instead, you must use

The ExecSQL method if the dataset is an instance of *TSQLDataSet* or *TSQLQuery*.

```
FixTicket.CommandText := 'DELETE FROM TrafficViolations WHERE (TicketID = 1099)';
FixTicket.ExecSQL;
FixTicket->CommandText = "DELETE FROM TrafficViolations WHERE (TicketID = 1099)";
FixTicket->ExecSQL();
```

The ExecProc method if the dataset is an instance of *TSQLStoredProc*.

```
SQLStoredProc1.StoredProcName := 'MyCommandWithNoResults';
SQLStoredProc1.ExecProc;
SQLStoredProc1->StoredProcName = "MyCommandWithNoResults";
SQLStoredProc1->ExecProc();
```

If you are executing the query or stored procedure multiple times, it is a good idea to set the Prepared property to *True*.

Specifying the Command to Execute (see page 1835)

Creating and Modifying Server Metadata (see page 1826)

3.2.3.12.8 Fetching Metadata into a dbExpress Dataset

To populate a unidirectional dataset with metadata from the database server, you must first indicate what data you want to see, using the SetSchemaInfo method. *SetSchemaInfo* takes three parameters:

- The type of schema information (metadata) you want to fetch. This can be a list of tables (*stTables*), a list of system tables (*stSysTables*), a list of stored procedures (*stProcedures*), a list of fields in a table (*stColumns*), a list of indexes (*stIndexes*), or a list of parameters used by a stored procedure (*stProcedureParams*). Each type of information uses a different set of fields to describe the items in the list. For details on the structures of these datasets, see The structure of metadata datasets (see page 1837).
- If you are fetching information about fields, indexes, or stored procedure parameters, the name of the table or stored procedure to which they apply. If you are fetching any other type of schema information, this parameter is nil.
- A pattern that must be matched for every name returned. This pattern is an SQL pattern such as 'Cust%', which uses the wildcards '%' (to match a string of arbitrary characters of any length) and '_' (to match a single arbitrary character). To use a literal percent or underscore in a pattern, the character is doubled (%% or __). If you do not want to use a pattern, this parameter can be nil.

If you are fetching schema information about tables (*stTables*), the resulting schema information can describe ordinary tables, system tables, views, and/or synonyms, depending on the value of the SQL connection's TableScope property.

The following call requests a table listing all system tables (server tables that contain metadata):

```
SQLDataSet1.SetSchemaInfo(stSysTable, "", "");
SQLDataSet1->SetSchemaInfo(stSysTable, "", "");
```

When you open the dataset after this call to *SetSchemaInfo*, the resulting dataset has a record for each table, with columns giving the table name, type, schema name, and so on. If the server does not use system tables to store metadata (for example MySQL), when you open the dataset it contains no records.

The previous example used only the first parameter. Suppose, Instead, you want to obtain a list of input parameters for a stored procedure named 'MyProc'. Suppose, further, that the person who wrote that stored procedure named all parameters using a prefix to indicate whether they were input or output parameters ('inName', 'outValue' and so on). You could call *SetSchemaInfo* as follows:

```
SQLDataSet1.SetSchemaInfo(stProcedureParams, "MyProc", "in%");
SQLDataSet1->SetSchemaInfo(stProcedureParams, "MyProc", "in%");
```

The resulting dataset is a table of input parameters with columns to describe the properties of each parameter.

Fetching data after using the dataset for metadata

There are two ways to return to executing queries or stored procedures with the dataset after a call to *SetSchemaInfo*:

- Change the CommandText property, specifying the query, table, or stored procedure from which you want to fetch data.
- Call *SetSchemaInfo*, setting the first parameter to *stNoSchema*. In this case, the dataset reverts to fetching the data specified by the current value of *CommandText*.

See Also

Obtaining Metadata (see page 1501)

3.2.3.12.9 Fetching the Data

Once you have specified the source of the data (see page 1836), you must fetch the data before your application can access

it. Once the dataset has fetched the data, data-aware controls linked to the dataset through a data source automatically display data values and client datasets linked to the dataset through a provider can be populated with records.

As with any dataset, there are two ways to fetch the data for a dbExpress dataset:

One way is to set the Active*property to True, either at design time in the* ***Object Inspector****, or in code at runtime:*

```
CustQuery.Active := True;
CustQuery->Active = true;
```

Another way is to call the Open method at runtime,

```
CustQuery.Open;
CustQuery->Open();
```

Use the *Active* property or the *Open* method with any unidirectional dataset that obtains records from the server. It does not matter whether these records come from a SELECT query (including automatically-generated queries when the *CommandType* is *ctTable*) or a stored procedure.

Preparing the dataset

Before a query or stored procedure can execute on the server, it must first be "prepared". Preparing the dataset means that *dbExpress* and the server allocate resources for the statement and its parameters. If *CommandType* is *ctTable*, this is when the dataset generates its SELECT query. Any parameters that are not bound by the server are folded into a query at this point.

Unidirectional datasets are automatically prepared when you set *Active* to *True* or call the *Open* method. When you close the dataset, the resources allocated for executing the statement are freed. If you intend to execute the query or stored procedure more than once, you can improve performance by explicitly preparing the dataset before you open it the first time. To explicitly prepare a dataset, set its Prepared property to *True*.

```
CustQuery.Prepared := True;
CustQuery->Prepared = true;
```

When you explicitly prepare the dataset, the resources allocated for executing the statement are not freed until you set *Prepared* to *False*.

Set the *Prepared* property to *False* if you want to ensure that the dataset is re-prepared before it executes (for example, if you change a parameter value or the *SortFieldNames* property).

Fetching multiple datasets

Some stored procedures return multiple sets of records. The dataset only fetches the first set when you open it. In order to access the other sets of records, call the NextRecordSet method:

```
var
  DataSet2: TCustomSQLDataSet;
  nRows: Integer;
begin
  DataSet2 := SQLStoredProc1.NextRecordSet;
  ...
TCustomSQLDataSet *DataSet2 = SQLStoredProc1->NextRecordSet();
```

NextRecordSet returns a newly created *TCustomSQLDataSet* component that provides access to the next set of records. That is, the first time you call *NextRecordSet*, it returns a dataset for the second set of records. Calling *NextRecordSet* returns a third dataset, and so on, until there are no more sets of records. When there are no additional datasets, *NextRecordSet* returns **nil**.

3.2.3.12.10 Representing the Records in a Table

When you want to represent all of the fields and all of the records in a single underlying database table, you can use either *TSQLDataSet* or *TSQLTable* to generate the query for you rather than writing the SQL yourself.

Note: If server performance is a concern, you may want to compose the query explicitly rather than relying on an automatically-generated query. Automatically-generated queries use wildcards rather than explicitly listing all of the fields in the table. This can result in slightly slower performance on the server. The wildcard (*) in automatically-generated queries is more robust to changes in the fields on the server.

Representing a table using TSQLDataSet

To make *TSQLDataSet* generate a query to fetch all fields and all records of a single database table, set the CommandType property to *ctTable*.

When *CommandType* is *ctTable*, *TSQLDataSet* generates a query based on the values of two properties:

- CommandText specifies the name of the database table that the *TSQLDataSet* object should represent.
- SortFieldNames lists the names of any fields to use to sort the data, in the order of significance.

For example, if you specify the following:

```
SQLDataSet1.CommandType := ctTable;
SQLDataSet1.CommandText := 'Employee';
SQLDataSet1.SortFieldNames := 'HireDate,Salary'
SQLDataSet1->CommandType = ctTable;
SQLDataSet1->CommandText = "Employee";
SQLDataSet1->SortFieldNames = "HireDate,Salary"
```

TSQLDataSet generates the following query, which lists all the records in the Employee table, sorted by HireDate and, within HireDate, by Salary:

```
select * from Employee order by HireDate, Salary
```

Representing a table using TSQLTable

When using *TSQLTable*, specify the table you want using the TableName property.

To specify the order of fields in the dataset, you must specify an index. There are two ways to do this:

- Set the IndexName property to the name of an index defined on the server that imposes the order you want.
- Set the IndexFieldNames property to a semicolon-delimited list of field names on which to sort. *IndexFieldNames* works like the *SortFieldNames* property of *TSQLDataSet*, except that it uses a semicolon instead of a comma as a delimiter.

Representing the Results of a Stored Procedure (see page 1833)

Representing the Results of a Query (see page 1832)

3.2.3.12.11 Representing the Results of a Query

Using a query is the most general way to specify a set of records. Queries are simply commands written in SQL. You can use either *TSQLDataSet* or *TSQLQuery* to represent the result of a query.

When using *TSQLDataSet*, set the CommandType property to *ctQuery* and assign the text of the query statement to the

CommandText property. When using *TSQLQuery*, assign the query to the SQL property instead. These properties work the same way for all general-purpose or query-type datasets. Specifying the query (see page 1613) discusses them in greater detail.

When you specify the query, it can include parameters, or variables, the values of which can be varied at design time or runtime. Parameters can replace data values that appear in the SQL statement. Using parameters in queries and supplying values for those parameters is discussed in Using parameters in queries (see page 1617).

SQL defines queries such as UPDATE queries that perform actions on the server but do not return records. Such queries are discussed in Executing commands that do not return records (see page 1829).

See Also

Representing the Results of a Stored Procedure (see page 1833)

3.2.3.12.12 Representing the Results of a Stored Procedure

Stored procedures are sets of SQL statements that are named and stored on an SQL server. How you indicate the stored procedure you want to execute depends on the type of unidirectional dataset you are using.

When using TSQLDataSet, to specify a stored procedure:

- Set the CommandType property to *ctStoredProc*.
- Specify the name of the stored procedure as the value of the CommandText property:

```
SQLDataSet1.CommandType := ctStoredProc;
SQLDataSet1.CommandText := 'MyStoredProcName';
SQLDataSet1->CommandType = ctStoredProc;
SQLDataSet1->CommandText = "MyStoredProcName";
```

When using TSQLStoredProc, you need only specify the name of the stored procedure as the value of the StoredProcName property.

```
SQLStoredProc1.StoredProcName := 'MyStoredProcName';
SQLStoredProc1->StoredProcName = "MyStoredProcName";
```

After you have identified a stored procedure, your application may need to enter values for any input parameters of the stored procedure or retrieve the values of output parameters after you execute the stored procedure. See Working with stored procedure parameters (see page 1625) for information about working with stored procedure parameters.

Representing the Results of a Query (see page 1832)

3.2.3.12.13 Setting Up Master/Detail Linked Relationships

There are two ways to use linked datasets to set up a master/detail relationship with a dbExpress dataset as the detail set. Which method you use depends on the type of unidirectional dataset (see page 1836) you are using. Once you have set up such a relationship, the unidirectional dataset (the "many" in a one-to-many relationship) provides access only to those records that correspond to the current record on the master set (the "one" in the one-to-many relationship).

TSQLDataSet and *TSQLQuery* require you to use a parameterized query to establish a master/detail relationship. This is the technique for creating such relationships on all query-type datasets. For details on creating master/detail relationships with query-type datasets, see Establishing master/detail relationships using parameters (see page 1593).

To set up a master/detail relationship where the detail set is an instance of *TSQLTable*, use the MasterSource and MasterFields properties, just as you would with any other table-type dataset. For details on creating master/detail relationships with table-type datasets, see Creating Master/detail Relationships (see page 1590).

3.2.3.12.14 Setting Up TSQLConnection

In order to describe a database connection in sufficient detail for TSQLConnection to open a connection, you must identify both the driver to use and a set of connection parameters the are passed to that driver.

Identifying the driver

The driver is identified by the DriverName property, which is the name of an installed *dbExpress* driver, such as ASA, ASE, INTERBASE, INFORMIX, ORACLE, MYSQL, MSSQL, DB2 or BlackfishSQL. BlackfishSQL uses the DbxClient driver, which is written entirely in Object Pascal. The rest of these databases use Dynalink drivers, which are partially written in Object Pascal. For Dynalink drivers, the driver name is associated with these files:

- The *dbExpress* driver. This is a dynamic-link library with a name like dbx*.dll. For example, the Interbase driver DLL begins with “dbxint” and the Oracle driver DLL begins with “dbxora”
- The dynamic-link library provided by the database vendor for client-side support.

The relationship between these files and the database name is stored in a file called dbxdrivers.ini, which is updated when you install a *dbExpress* driver. Typically, you do not need to worry about these files because the SQL connection component looks them up in dbxdrivers.ini when given the value of *DriverName*. When you set the *DriverName* property, *TSQLConnection* automatically sets the LibraryName and VendorLib properties to the names of the associated dlls. Once *LibraryName* and *VendorLib* have been set, your application does not need to rely on dbxdrivers.ini. (That is, you do not need to deploy dbxdrivers.ini with your application unless you set the *DriverName* property at runtime.)

Specifying connection parameters

The Params property is a string list that lists name/value pairs. Each pair has the form *Name*=*Value*, where *Name* is the name of the parameter, and *Value* is the value you want to assign.

The particular parameters you need depend on the database server you are using. However, one particular parameter, *Database*, is required for all servers. Its value depends on the server you are using. For example, with InterBase, *Database* is the name of the .gdb file, with ORACLE it is the entry in TNSNames.ora, while with DB2, it is the client-side node name.

Other typical parameters include the *User_Name* (the name to use when logging in), *Password* (the password for *User_Name*), *HostName* (the machine name or IP address of where the server is located), and *TransIsolation* (the degree to which transactions you introduce are aware of changes made by other transactions). When you specify a driver name, the *Params* property is preloaded with all the parameters you need for that driver type, initialized to default values.

Because *Params* is a string list, at design time you can double-click on the *Params* property in the **Object Inspector** to edit the parameters using the String List editor. At runtime, use the Params.Values property to assign values to individual parameters.

Naming a connection description

Although you can always specify a connection using only the *DatabaseName* and *Params* properties, it can be more convenient to name a specific combination and then just identify the connection by name. You can name *dbExpress* database and parameter combinations, which are then saved in a file called dbxconnections.ini. The name of each combination is called a

connection name.

Once you have defined the connection name, you can identify a database connection by simply setting the ConnectionName property to a valid connection name. Setting *ConnectionName* automatically sets the *DriverName* and *Params* properties. Once *ConnectionName* is set, you can edit the *Params* property to create temporary differences from the saved set of parameter values, but changing the *DriverName* property clears both *Params* and *ConnectionName*.

One advantage of using connection names arises when you develop your application using one database (for example Local InterBase), but deploy it for use with another (such as ORACLE). In that case, *DriverName* and *Params* will likely differ on the system where you deploy your application from the values you use during development. You can switch between the two connection descriptions easily by using two versions of the dbxconnections.ini file. At design-time, your application loads the *DriverName* and *Params* from the design-time version of dbxconnections.ini. Then, when you deploy your application, it loads these values from a separate version of dbxconnections.ini that uses the "real" database. However, for this to work, you must instruct your connection component to reload the *DriverName* and *Params* properties at runtime. There are two ways to do this:

- Set the LoadParamsOnConnect property to *True*. This causes *TSQLConnection* to automatically set *DriverName* and *Params* to the values associated with *ConnectionName* in dbxconnections.ini when the connection is opened.
- Call the LoadParamsFromIniFile method. This method sets *DriverName* and *Params* to the values associated with *ConnectionName* in dbxconnections.ini (or in another file that you specify). You might choose to use this method if you want to then override certain parameter values before opening the connection.

Using the Connection Editor

The relationships between connection names and their associated driver and connection parameters is stored in the dbxconnections.ini file. You can create or modify these associations using the Connection Editor.

To display the Connection Editor, double-click on the *TSQLConnection* component. The Connection Editor appears, with a drop-down list containing all available drivers, a list of connection names for the currently selected driver, and a table listing the connection parameters for the currently selected connection name.

You can use this dialog to indicate the connection to use by selecting a driver and connection name. Once you have chosen the configuration you want, click the Test Connection button to check that you have chosen a valid configuration.

In addition, you can use this dialog to edit the named connections in dbxconnections.ini:

- Edit the parameter values in the parameter table to change the currently selected named connection. When you exit the dialog by clicking OK, the new parameter values are saved to dbxconnections.ini.
- Click the Add Connection button to define a new named connection. A dialog appears where you specify the driver to use and the name of the new connection. Once the connection is named, edit the parameters to specify the connection you want and click the OK button to save the new connection to dbxconnections.ini.
- Click the Delete Connection button to delete the currently selected named connection from dbxconnections.ini.
- Click the Rename Connection button to change the name of the currently selected named connection. Note that any edits you have made to the parameters are saved with the new name when you click the OK button.

Connecting to Databases (see page 1506)

3.2.3.12.15 Specifying the Command to Execute

With unidirectional datasets, the way you specify the command to execute is the same whether the command results in a dataset or not. That is:

When using TSQLDataSet, use the CommandType and CommandText properties to specify the command:

- If *CommandType* is *ctQuery*, *CommandText* is the SQL statement to pass to the server.
- If *CommandType* is *ctStoredProc*, *CommandText* is the name of a stored procedure to execute.

When using TSQLQuery, use the SQL property to specify the SQL statement to pass to the server.

When using TSQLStoredProc, use the StoredProcName property to specify the name of the stored procedure to execute.

Just as you specify the command in the same way as when you are retrieving records, you work with query parameters (see page 1617) or stored procedure parameters (see page 1625) the same way as with queries and stored procedures that return records.

See Also

Executing the Command (see page 1829)

Creating and Modifying Server Metadata (see page 1826)

3.2.3.12.16 Specifying What Data to Display

There are a number of ways to specify what data a dbExpress dataset represents. Which method you choose depends on the type of unidirectional dataset (see page 1836) you are using and whether the information comes from a single database table, the results of a query, or from a stored procedure.

When you work with a TSQLDataSet component, use the CommandType property to indicate where the dataset gets its data. *CommandType* can take any of the following values:

- *ctQuery*: When *CommandType* is *ctQuery*, *TSQLDataSet* executes a query you specify. If the query is a SELECT command, the dataset contains the resulting set of records.
- *ctTable*: When *CommandType* is *ctTable*, *TSQLDataSet* retrieves all of the records from a specified table.
- *ctStoredProc*: When *CommandType* is *ctStoredProc*, *TSQLDataSet* executes a stored procedure. If the stored procedure returns a cursor, the dataset contains the returned records.

The following topics describe how you can specify a set of records for each type of source:

- Representing the results of a query (see page 1832)
- Representing the records in a table (see page 1832)
- Representing the results of a stored procedure (see page 1833)

  Note: You can also populate the unidirectional dataset with metadata about what is available on the server. For information on how to do this, see Fetching metadata into a dbExpress dataset (see page 1830).

3.2.3.12.17 Types of dbExpress Datasets

The *dbExpress* category of the **Tool palette** contains four types of unidirectional dataset: TSQLDataSet, TSQLQuery, TSQLTable, and TSQLStoredProc.

TSQLDataSet is the most general of the four. You can use an SQL dataset to represent any data available through *dbExpress*, or to send commands to a database accessed through *dbExpress*. This is the recommended component to use for working with database tables in new database applications.

TSQLQuery is a query-type dataset (see page 1618) that encapsulates an SQL statement and enables applications to access the resulting records, if any.

TSQLTable is a table-type dataset (see page 1620) that represents all of the rows and columns of a single database table.

TSQLStoredProc is a stored procedure-type dataset (see page 1618) that executes a stored procedure defined on a database server.

Note: The *dbExpress* page also includes TSimpleDataSet, which is not a unidirectional dataset. Rather, it is a client dataset that uses a unidirectional dataset internally to access its data.

3.2.3.12.18 The Structure of Metadata Datasets

For each type of metadata you can access using *TSQLDataSet*, there is a predefined set of columns (fields) that are populated with information about the items of the requested type.

Information about tables

When you request information about tables (*stTables* or *stSysTables*), the resulting dataset includes a record for each table. It has the following columns:

Columns in tables of metadata listing tables

Column name	Field type	Contents
RECNO	ftInteger	A record number that uniquely identifies each record.
CATALOG_NAME	ftString	The name of the catalog (database) that contains the table. This is the same as the *Database* parameter on an SQL connection component.
SCHEMA_NAME	ftString	The name of the schema that identifies the owner of the table.
TABLE_NAME	ftString	The name of the table. This field determines the sort order of the dataset.
TABLE_TYPE	ftInteger	Identifies the type of table. It is a sum of one or more of the following values: 1: Table 2: View 4: System table 8: Synonym 16: Temporary table 32: Local table.

Information about stored procedures

When you request information about stored procedures (*stProcedures*), the resulting dataset includes a record for each stored procedure. It has following columns:

Columns in tables of metadata listing stored procedures

Column name	Field type	Contents
RECNO	ftInteger	A record number that uniquely identifies each record.

CATALOG_NAME	ftString	The name of the catalog (database) that contains the stored procedure. This is the same as the *Database* parameter on an SQL connection component.
SCHEMA_NAME	ftString	The name of the schema that identifies the owner of the stored procedure.
PROC_NAME	ftString	The name of the stored procedure. This field determines the sort order of the dataset.
PROC_TYPE	ftInteger	Identifies the type of stored procedure. It is a sum of one or more of the following values: 1: Procedure 2: Function 4: Package 8: System procedure
IN_PARAMS	ftSmallint	The number of input parameters
OUT_PARAMS	ftSmallint	The number of output parameters.

Information about fields

When you request information about the fields in a specified table (*stColumns*), the resulting dataset includes a record for each field. It includes the following columns:

Columns in tables of metadata listing fields

Column name	Field type	Contents
RECNO	ftInteger	A record number that uniquely identifies each record.
CATALOG_NAME	ftString	The name of the catalog (database) that contains the table whose fields you listing. This is the same as the *Database* parameter on an SQL connection component.
SCHEMA_NAME	ftString	The name of the schema that identifies the owner of the field.
TABLE_NAME	ftString	The name of the table that contains the fields.
COLUMN_NAME	ftString	The name of the field. This value determines the sort order of the dataset.
COLUMN_POSITION	ftSmallint	The position of the column in its table.
COLUMN_TYPE	ftInteger	Identifies the type of value in the field. It is a sum of one or more of the following: 1: Row ID 2: Row Version 4: Auto increment field 8: Field with a default value
COLUMN_DATATYPE	ftSmallint	The datatype of the column. This is one of the logical field type constants defined in sqllinks.pas.
COLUMN_TYPENAME	ftString	A string describing the datatype. This is the same information as contained in COLUMN_DATATYPE and COLUMN_SUBTYPE, but in a form used in some DDL statements.
COLUMN_SUBTYPE	ftSmallint	A subtype for the column's datatype. This is one of the logical subtype constants defined in sqllinks.pas.
COLUMN_PRECISION	ftInteger	The size of the field type (number of characters in a string, bytes in a bytes field, significant digits in a BCD value, members of an ADT field, and so on).
COLUMN_SCALE	ftSmallint	The number of digits to the right of the decimal on BCD values, or descendants on ADT and array fields.
COLUMN_LENGTH	ftInteger	The number of bytes required to store field values.
COLUMN_NULLABLE	ftSmallint	A Boolean that indicates whether the field can be left blank (0 means the field requires a value).

Information about indexes

When you request information about the indexes on a table (stIndexes), the resulting dataset includes a record for each field in each record. (Multi-record indexes are described using multiple records) The dataset has the following columns:

Columns in tables of metadata listing indexes

Column name	Field type	Contents
RECNO	ftInteger	A record number that uniquely identifies each record.
CATALOG_NAME	ftString	The name of the catalog (database) that contains the index. This is the same as the *Database* parameter on an SQL connection component.
SCHEMA_NAME	ftString	The name of the schema that identifies the owner of the index.
TABLE_NAME	ftString	The name of the table for which the index is defined.
INDEX_NAME	ftString	The name of the index. This field determines the sort order of the dataset.
PKEY_NAME	ftString	Indicates the name of the primary key.
COLUMN_NAME	ftString	The name of the field (column) in the index.
COLUMN_POSITION	ftSmallint	The position of this field in the index.
INDEX_TYPE	ftSmallint	Identifies the type of index. It is a sum of one or more of the following values: 1: Non-unique 2: Unique 4: Primary key
SORT_ORDER	ftString	Indicates that the index is ascending (a) or descending (d).
FILTER	ftString	Describes a filter condition that limits the indexed records.

Information about stored procedure parameters

When you request information about the parameters of a stored procedure (*stProcedureParams*), the resulting dataset includes a record for each parameter. It has the following columns:

Columns in tables of metadata listing parameters

Column name	Field type	Contents
RECNO	ftInteger	A record number that uniquely identifies each record.
CATALOG_NAME	ftString	The name of the catalog (database) that contains the stored procedure. This is the same as the *Database* parameter on an SQL connection component.
SCHEMA_NAME	ftString	The name of the schema that identifies the owner of the stored procedure.
PROC_NAME	ftString	The name of the stored procedure that contains the parameter.
PARAM_NAME	ftString	The name of the parameter. This field determines the sort order of the dataset.
PARAM_TYPE	ftSmallint	Identifies the type of parameter. This is the same as a *TParam* object's *ParamType* property.
PARAM_DATATYPE	ftSmallint	The datatype of the parameter. This is one of the logical field type constants defined in sqllinks.pas.
PARAM_SUBTYPE	ftSmallint	A subtype for the parameter's datatype. This is one of the logical subtype constants defined in sqllinks.pas.
PARAM_TYPENAME	ftString	A string describing the datatype. This is the same information as contained in PARAM_DATATYPE and PARAM_SUBTYPE, but in a form used in some DDL statements.
PARAM_PRECISION	ftInteger	The maximum number of digits in floating-point values or bytes (for strings and Bytes fields).
PARAM_SCALE	ftSmallint	The number of digits to the right of the decimal on floating-point values.
PARAM_LENGTH	ftInteger	The number of bytes required to store parameter values.
PARAM_NULLABLE	ftSmallint	A Boolean that indicates whether the parameter can be left blank (0 means the parameter requires a value).

Information about Oracle packages

Columns in tables of metadata listing stored procedures

Column Name	Field type	Contents
RECNO	ftInteger	A record number that uniquely identifies each record.
CATALOG_NAME	ftString	The name of the catalog (database) that contains the package. This is the same as the *Database* parameter on an SQL connection component.
SCHEMA_NAME	ftString	The name of the schema that identifies the owner of the package.
OBJECT_NAME	ftString	The name of the package. This field determines the sort order of the dataset.

Accessing Schema Information (see page 1824)

3.2.3.13 Using XML in database applications

Topics

Name	Description
Converting XML Documents into Data Packets (see page 1841)	Once you have created a transformation file (see page 1843) that indicates how to transform an XML document into a data packet, you can create data packets for any XML document that conforms to the schema used in the transformation. These data packets can then be assigned to a client dataset and saved to a file so that they form the basis of a file-based database application (see page 1564). The TXMLTransform component transforms an XML document into a data packet according to the mapping in a transformation file. **Note:** You can also use *TXMLTransform* to convert a data packet that appears in XML format... more (see page 1841)
Defining Transformations (see page 1843)	Before you can convert between data packets and XML documents, you must define the relationship between the metadata in a data packet and the nodes of the corresponding XML document (see page 1843). A description of this relationship is stored in a special XML document called a transformation. Each transformation file contains two things: the mapping between the nodes in an XML schema and the fields in a data packet, and a skeletal XML document that represents the structure for the results of the transformation. A transformation is a one-way mapping: from an XML schema or document to a data packet or... more (see page 1843)
Mapping Between XML Nodes and Data Packet Fields (see page 1843)	XML provides a text-based way to store or describe structured data. Datasets provide another way to store and describe structured data. To convert an XML document into a dataset, therefore, you must identify the correspondences between the nodes in an XML document and the fields in a dataset. Consider, for example, an XML document that represents a set of email messages. It might look like the following (containing a single message):
Using an XML Document as the Client of a Provider (see page 1845)	The TXMLTransformClient component acts as an adapter to let you use an XML document (or set of documents) as the client for an application server (or simply as the client of a dataset to which it connects via a *TDataSetProvider* component). That is, *TXMLTransformClient* lets you publish database data as an XML document and to make use of update requests (insertions or deletions) from an external application that supplies them in the form of XML documents. To specify the provider from which the *TXMLTransformClient* object fetches data and to which it applies updates, set the ProviderName property. As with the... more (see page 1845)
Using an XML Document as the Source for a Provider (see page 1846)	The TXMLTransformProvider component lets you use an XML document as if it were a database table. *TXMLTransformProvider* packages the data from an XML document and applies updates from clients back to that XML document. It appears to clients such as client datasets or XML brokers like any other provider component. For information on provider components, see Using Provider Components (see page 1819). For information on using provider components with client datasets, see Using a Client Dataset with a Provider (see page 1732). You can specify the XML document from which the XML provider provides data and to which it applies updates using the XMLDataFile... more (see page 1846)

Using XML in Database Applications (see page 1847)	In addition to the support for connecting to database servers (see page 1506), Delphi lets you work with XML documents as if they were database servers. XML (Extensible Markup Language) is a markup language for describing structured data. XML documents provide a standard, transportable format for data that is used in Web applications, business-to-business communication, and so on. For information on Delphi's support for working directly with XML documents, see Working with XML Documents. (see page 2352) Support for working with XML documents in database applications is based on a set of components that can convert data packets (the *Data* property of a client dataset)... more (see page 1847)
Using XMLMapper (see page 1848)	The XML mapper utility, xmlmapper.exe, lets you define mappings in three ways: • From an existing XML schema (or document) to a client dataset that you define. This is useful when you want to create a database application to work with data for which you already have an XML schema. • From an existing data packet to a new XML schema you define. This is useful when you want to expose existing database information in XML, for example to create a new business-to-business communication system. • Between an existing XML schema and an existing data packet. This is useful when you have an... more (see page 1848)

3.2.3.13.1 Converting XML Documents into Data Packets

Once you have created a transformation file (see page 1843) that indicates how to transform an XML document into a data packet, you can create data packets for any XML document that conforms to the schema used in the transformation. These data packets can then be assigned to a client dataset and saved to a file so that they form the basis of a file-based database application (see page 1564).

The TXMLTransform component transforms an XML document into a data packet according to the mapping in a transformation file.

Note: You can also use *TXMLTransform* to convert a data packet that appears in XML format into an arbitrary XML document.

Specifying the source XML document

There are three ways to specify the source XML document:

- If the source document is an .xml file on disk, you can use the SourceXmlFile property.
- If the source document is an in-memory string of XML, you can use the SourceXml property.
- If you have an IDOMDocument interface for the source document, you can use the SourceXmlDocument property.

TXMLTransform checks these properties in the order listed above. That is, it first checks for a file name in the *SourceXmlFile* property. Only if *SourceXmlFile* is an empty string does it check the *SourceXml* property. Only if *SourceXml* is an empty string does it then check the *SourceXmlDocument* property.

Specifying the transformation

There are two ways to specify the transformation that converts the XML document into a data packet:

- Set the TransformationFile property to indicate a transformation file that was created using xmlmapper.exe.
- Set the TransformationDocument property if you have an *IDOMDocument* interface for the transformation.

TXMLTransform checks these properties in the order listed above. That is, it first checks for a file name in the *TransformationFile* property. Only if *TransformationFile* is an empty string does it check the *TransformationDocument* property.

Obtaining the resulting data packet

To cause *TXMLTransform* to perform its transformation and generate a data packet, you need only read the Data property. For example, the following code uses an XML document and transformation file to generate a data packet, which is then assigned to

a client dataset:

```
XMLTransform1.SourceXMLFile := 'CustomerDocument.xml';
XMLTransform1.TransformationFile := 'CustXMLToCustTable.xtr';
ClientDataSet1.XMLData := XMLTransform1.Data;
XMLTransform1->SourceXMLFile = "CustomerDocument.xml";
XMLTransform1->TransformationFile = "CustXMLToCustTable.xtr";
ClientDataSet1->XMLData = XMLTransform1->Data;
```

Converting user-defined nodes

When you define a transformation using xmlmapper.exe (see page 1848), you can specify that some of the nodes in the XML document are "user-defined." User-defined nodes are nodes for which you want to provide the transformation in code rather than relying on a straightforward node-value-to-field-value translation.

You can provide the code to translate user-defined nodes using the OnTranslate event. The *OnTranslate* event handler is called every time the *TXMLTransform* component encounters a user-defined node in the XML document. In the OnTranslate event handler, you can read the source document and specify the resulting value for the field in the data packet.

For example, the following *OnTranslate* event handler converts a node in the XML document with the following form

```
<FullName>
   <Title> </Title>
   <FirstName> </FirstName>
   <LastName> </LastName>
</FullName>
```

into a single field value:

```
procedure TForm1.XMLTransform1Translate(Sender: TObject; Id: String; SrcNode: IDOMNode;
  var Value: String; DestNode: IDOMNode);
var
  CurNode: IDOMNode;
begin
  if Id = 'FullName' then
  begin
    Value = '';
    if SrcNode.hasChildNodes then
    begin
      CurNode := SrcNode.firstChild;
      Value := Value + CurNode.nodeValue;
      while CurNode <> SrcNode.lastChild do
      begin
        CurNode := CurNode.nextSibling;
        Value := Value + ' ';
        Value := Value + CurNode.nodeValue;
      end;
    end;
  end;
end;
void __fastcall TForm1::XMLTransform1Translate(TObject *Sender, AnsiString Id,
_di_IDOMNode SrcNode, AnsiString &Value, _di_IDOMNode DestNode)
{
  if (Id == "FullName")
  {
    Value = "";
    if (SrcNode.hasChildNodes)
    {
      _di_IXMLDOMNode CurNode = SrcNode.firstChild;
      Value = SrcValue + AnsiString(CurNode.nodeValue);
      while (CurNode != SrcNode.lastChild)
      {
        CurNode = CurNode.nextSibling;
        Value = Value + AnsiString(" ");
        Value = Value + AnsiString(CurNode.nodeValue);
      }
    }
```

```
  }
}
```

Defining Transformations (see page 1843)

Using an XML Document as the Source for a Provider (see page 1846)

Using an XML Document as the Client of a Provider (see page 1845)

3.2.3.13.2 Defining Transformations

Before you can convert between data packets and XML documents, you must define the relationship between the metadata in a data packet and the nodes of the corresponding XML document (see page 1843). A description of this relationship is stored in a special XML document called a transformation.

Each transformation file contains two things: the mapping between the nodes in an XML schema and the fields in a data packet, and a skeletal XML document that represents the structure for the results of the transformation. A transformation is a one-way mapping: from an XML schema or document to a data packet or from the metadata in a data packet to an XML schema. Often, you create transformation files in pairs: one that maps from XML to data packet, and one that maps from data packet to XML.

In order to create the transformation files for a mapping, use the XMLMapper utility (see page 1848) that ships in the bin directory.

Using an XML Document as the Source for a Provider (see page 1846)

Using an XML Document as the Client of a Provider (see page 1845)

3.2.3.13.3 Mapping Between XML Nodes and Data Packet Fields

XML provides a text-based way to store or describe structured data. Datasets provide another way to store and describe structured data. To convert an XML document into a dataset, therefore, you must identify the correspondences between the nodes in an XML document and the fields in a dataset.

Consider, for example, an XML document that represents a set of email messages. It might look like the following (containing a single message):

```
<?xml version="1.0" standalone="yes" ?>
<email>
   <head>
      <from>
         <name>Dave Boss</name>
         <address>dboss@MyCo.com</address>
      </from>
      <to>
         <name>Joe Engineer</name>
         <address>jengineer@MyCo.com</address>
      </to>
      <cc>
         <name>Robin Smith/name>
         <address>rsmith@MyCo.com</address>
      </cc>
      <cc>
         <name>Leonard Devon</name>
         <address>ldevon@MyCo.com</address>
      </cc>
   </head>
```

```
   <body>
      <subject>XML components</subject>
      <content>
        Joe,
        Attached is the specification for the XML component support in Delphi.
        This looks like a good solution to our buisness-to-buisness application!
        Also attached, please find the project schedule. Do you think its reasonable?
           Dave.
      </content>
      <attachment attachfile="XMLSpec.txt"/>
      <attachment attachfile="Schedule.txt"/>
   </body>
</email>
```

One natural mapping between this document and a dataset would map each e-mail message to a single record. The record would have fields for the sender's name and address. Because an e-mail message can have multiple recipients, the recipient (<to> would map to a nested dataset. Similarly, the cc list maps to a nested dataset. The subject line would map to a string field while the message itself (<content>) would probably be a memo field. The names of attachment files would map to a nested dataset because one message can have several attachments. Thus, the e-mail above would map to a dataset something like the following:

SenderName	SenderAddress	To	CC	Subject	Content	Attach
Dave Boss	dboss@MyCo.Com	(DataSet)	(DataSet)	XML components	(MEMO)	(DataSet)

where the nested dataset in the "To" field is

Name	Address
Joe Engineer	jengineer@MyCo.Com

the nested dataset in the "CC" field is

Name	Address
Robin Smith	rsmith@MyCo.Com
Leonard Devon	ldevon@MyCo.Com

and the nested dataset in the "Attach" field is

Attachfile
XMLSpec.txt
Schedule.txt

Defining such a mapping involves identifying those nodes of the XML document that can be repeated and mapping them to nested datasets. Tagged elements that have values and appear only once (such as <content>...</content>) map to fields whose datatype reflects the type of data that can appear as the value. Attributes of a tag (such as the AttachFile attribute of the attachment tag) also map to fields.

Note that not all tags in the XML document appear in the corresponding dataset. For example, the <head>...<head/> element has no corresponding element in the resulting dataset. Typically, only elements that have values, elements that can be repeated, or the attributes of a tag map to the fields (including nested dataset fields) of a dataset. The exception to this rule is when a parent node in the XML document maps to a field whose value is built up from the values of the child nodes. For example, an XML document might contain a set of tags such as

```
<FullName>
   <Title> Mr. </Title>
   <FirstName> John </FirstName>
   <LastName> Smith </LastName>
```

```
</FullName>
```

which could map to a single dataset field with the value

```
Mr. John Smith
```

3.2.3.13.4 Using an XML Document as the Client of a Provider

The TXMLTransformClient component acts as an adapter to let you use an XML document (or set of documents) as the client for an application server (or simply as the client of a dataset to which it connects via a *TDataSetProvider* component). That is, *TXMLTransformClient* lets you publish database data as an XML document and to make use of update requests (insertions or deletions) from an external application that supplies them in the form of XML documents.

To specify the provider from which the *TXMLTransformClient* object fetches data and to which it applies updates, set the ProviderName property. As with the *ProviderName* property of a client dataset, *ProviderName* can be the name of a provider on a remote application server or it can be a local provider in the same form or data module as the *TXMLTransformClient* object. For information about providers, see Using Provider Components (see page 1819).

If the provider is on a remote application server, you must use a DataSnap connection component to connect to that application server. Specify the connection component using the RemoteServer property. For information on DataSnap connection components, see Connecting to the Application Server (see page 1517).

Fetching an XML document from a provider

TXMLTransformClient uses an internal *TXMLTransform* component to translate data packets from the provider into an XML document. You can access this *TXMLTransform* component as the value of the TransformGetData property.

Before you can create an XML document that represents the data from a provider, you must specify the transformation file (see page 1843) that *TransformGetData* uses to translate the data packet into the appropriate XML format. You do this by setting the *TXMLTransform* component's TransformationFile or TransformationDocument property, just as when using a stand-alone TXMLTransform component (see page 1841). If that transformation includes any user-defined nodes, you will want to supply *TransformGetData* with an OnTranslate event handler as well.

There is no need to specify the source document for *TransformGetData*, *TXMLTransformClient* fetches that from the provider. However, if the provider expects any input parameters, you may want to set them before fetching the data. Use the SetParams method to supply these input parameters before you fetch data from the provider. *SetParams* takes two arguments: a string of XML from which to extract parameter values, and the name of a transformation file to translate that XML into a data packet. *SetParams* uses the transformation file to convert the string of XML into a data packet, and then extracts the parameter values from that data packet.

Note: You can override either of these arguments if you want to specify the parameter document or transformation in another way. Simply set one of the properties on TransformSetParams property to indicate the document that contains the parameters or the transformation to use when converting them, and then set the argument you want to override to an empty string when you call *SetParams*. For details on the properties you can use, see Converting XML Documents Into Data Packets (see page 1841).

Once you have configured *TransformGetData* and supplied any input parameters, you can call the GetDataAsXml method to fetch the XML. *GetDataAsXml* sends the current parameter values to the provider, fetches a data packet, converts it into an XML document, and returns that document as a string. You can save this string to a file:

```
var
  XMLDoc: TFileStream;
  XML: string;
begin
  XMLTransformClient1.ProviderName := 'Provider1';
```

```
    XMLTransformClient1.TransformGetData.TransformationFile := 'CustTableToCustXML.xtr';
    XMLTransformClient1.TransFormSetParams.SourceXmlFile := 'InputParams.xml';
    XMLTransformClient1.SetParams('', 'InputParamsToDP.xtr');
    XML := XMLTransformClient1.GetDataAsXml('');
    XMLDoc := TFileStream.Create('Customers.xml', fmCreate or fmOpenWrite);
    try
      XMLDoc.Write(XML, Length(XML));
    finally
      XMLDoc.Free;
    end;
  end;
  XMLTransformClient1->ProviderName = "Provider1";
  XMLTransformClient1->TransformGetData->TransformationFile = "CustTableToCustXML.xtr";
  XMLTransformClient1->TransFormSetParams->SourceXmlFile = "InputParams.xml";
  XMLTransformClient1->SetParams("", "InputParamsToDP.xtr");
  AnsiString XML = XMLTransformClient1->GetDataAsXml("");
  TFileStream pXMLDoc = new TFileStream("Customers.xml", fmCreate || fmOpenWrite);
  __try
  {
    pXMLDoc->Write(XML.c_str(), XML.Length());
  }
  __finally
  {
    delete pXMLDoc;
  }
```

Applying updates from an XML document to a provider

TXMLTransformClient also lets you insert all of the data from an XML document into the provider's dataset or to delete all of the records in an XML document from the provider's dataset. To perform these updates, call the ApplyUpdates*method, passing in*

- A string whose value is the contents of the XML document with the data to insert or delete.
- The name of a transformation file that can convert that XML data into an insert or delete delta packet. (When you define the transformation file using the XML mapper utility, you specify whether the transformation is for an insert or delete delta packet.)
- The number of update errors that can be tolerated before the update operation is aborted. If fewer than the specified number of records can't be inserted or deleted, *ApplyUpdates* returns the number of actual failures. If more than the specified number of records can't be inserted or deleted, the entire update operation is rolled back, and no update is performed.

The following call transforms the XML document Customers.xml into a delta packet and applies all updates regardless of the number of errors:

```
StringList1.LoadFromFile('Customers.xml');
nErrors := ApplyUpdates(StringList1.Text, 'CustXMLToInsert.xtr', -1);
StringList1->LoadFromFile("Customers.xml");
nErrors = ApplyUpdates(StringList1->Text, "CustXMLToInsert.xtr", -1);
```

Defining Transformations (see page 1843)

Converting XML Documents into Data Packets (see page 1841)

Using an XML Document as the Source for a Provider (see page 1846)

3.2.3.13.5 Using an XML Document as the Source for a Provider

The TXMLTransformProvider component lets you use an XML document as if it were a database table. *TXMLTransformProvider* packages the data from an XML document and applies updates from clients back to that XML document. It appears to clients such as client datasets or XML brokers like any other provider component. For information on provider components, see Using Provider Components (see page 1819). For information on using provider components with client datasets, see Using a Client Dataset with a Provider (see page 1732).

You can specify the XML document from which the XML provider provides data and to which it applies updates using the

XMLDataFile property.

TXMLTransformProvider components use internal *TXMLTransform* components to translate between data packets and the source XML document: one to translate the XML document into data packets, and one to translate data packets back into the XML format of the source document after applying updates. These two *TXMLTransform* components can be accessed using the TransformRead and TransformWrite properties, respectively.

When using *TXMLTransformProvider*, you must specify the transformations that these two *TXMLTransform* components use to translate between data packets and the source XML document. You do this by setting the *TXMLTransform* component's TransformationFile or TransformationDocument property, just as when using a stand-alone TXMLTransform component (see page 1841).

In addition, if the transformation includes any user-defined nodes, you must supply an OnTranslate event handler to the internal *TXMLTransform* components.

You do not need to specify the source document on the *TXMLTransform* components that are the values of *TransformRead* and *TransformWrite*. For *TransformRead*, the source is the file specified by the provider's *XMLDataFile* property (although, if you set *XMLDataFile* to an empty string, you can supply the source document using *TransformRead.XmlSource* or *TransformRead.XmlSourceDocument*). For *TransformWrite*, the source is generated internally by the provider when it applies updates.

3.2.3.13.6 Using XML in Database Applications

In addition to the support for connecting to database servers (see page 1506), Delphi lets you work with XML documents as if they were database servers. XML (Extensible Markup Language) is a markup language for describing structured data. XML documents provide a standard, transportable format for data that is used in Web applications, business-to-business communication, and so on. For information on Delphi's support for working directly with XML documents, see Working with XML Documents. (see page 2352)

Support for working with XML documents in database applications is based on a set of components that can convert data packets (the *Data* property of a client dataset) into XML documents and convert XML documents into data packets. To use these components, you must first define the transformation (see page 1843) between the XML document and the data packet. Once you have defined the transformation, you can use special components to

- convert XML documents into data packets (see page 1841).
- provide data from and resolve updates to an XML document (see page 1846).
- use an XML document as the client of a provider (see page 1845).

3.2.3.13.7 Using XMLMapper

The XML mapper utility, xmlmapper.exe, lets you define mappings in three ways:

- From an existing XML schema (or document) to a client dataset that you define. This is useful when you want to create a database application to work with data for which you already have an XML schema.
- From an existing data packet to a new XML schema you define. This is useful when you want to expose existing database information in XML, for example to create a new business-to-business communication system.
- Between an existing XML schema and an existing data packet. This is useful when you have an XML schema and a database that both describe the same information and you want to make them work together.

  Note: XML mapper relies on two .DLLs (midas.dll and msxml.dll) to work correctly. Be sure that you have both of these .DLLs installed before you try to use xmlmapper.exe. In addition, msxml.dll must be registered as a COM server. You can register it using Regsvr32.exe.

Loading an XML schema or data packet

Before you can define a mapping and generate a transformation file, you must first load descriptions of the XML document and the data packet between which you are mapping.

You can load an XML document or schema by choosing **File** ▸ **Open** and selecting the document or schema in the resulting dialog.

You can load a data packet by choosing **File** ▸ **Open** and selecting a data packet file in the resulting dialog. (The data packet is simply the file generated when you call a client dataset's *SaveToFile* method.) If you have not saved the data packet to disk, you can fetch the data packet directly from the application server of a multi-tiered application by right-clicking in the Datapacket pane and choosing Connect To Remote Server.

You can load only an XML document or schema, only a data packet, or you can load both. If you load only one side of the mapping, XML mapper can generate a natural mapping for the other side.

Defining mappings

The mapping between an XML document and a data packet need not include all of the fields in the data packet or all of the tagged elements in the XML document. Therefore, you must first specify those elements that are mapped. To specify these elements, first select the Mapping page in the central pane of the dialog.

To specify the elements of an XML document or schema that are mapped to fields in a data packet, select the Sample or Structure tab of the XML document pane and double-click on the nodes for elements that map to data packet fields.

To specify the fields of the data packet that are mapped to tagged elements or attributes in the XML document, double-click on the nodes for those fields in the Datapacket pane.

If you have only loaded one side of the mapping (the XML document or the data packet), you can generate the other side after you have selected the nodes that are mapped.

- If you are generating a data packet from an XML document, you first define attributes for the selected nodes that determine the types of fields to which they correspond in the data packet. In the center pane, select the Node Repository page. Select each node that participates in the mapping and indicate the attributes of the corresponding field. If the mapping is not

straightforward (for example, a node with subnodes that corresponds to a field whose value is built from those subnodes), check the User Defined Translation check box. You will need to write an event handler later to perform the transformation on user defined nodes. Once you have specified the way nodes are to be mapped, choose **Create ▸ Datapacket from XML**. The corresponding data packet is automatically generated and displayed in the Datapacket pane.

- If you are generating an XML document from a data packet, choose **Create ▸ XML from Datapacket**. A dialog appears where you can specify the names of the tags and attributes in the XML document that correspond to fields, records, and datasets in the data packet. For field values, the way you name them indicates whether they map to a tagged element with a value or to an attribute. Names that begin with an @ symbol map to attributes of the tag that corresponds to the record, while names that do not begin with an @ symbol map to tagged elements that have values and that are nested within the element for the record.
- If you have loaded both an XML document and a data packet (client dataset file), be sure you select corresponding nodes in the same order. The corresponding nodes should appear next to each other in the table at the top of the Mapping page.

Once you have loaded or generated both the XML document and the data packet and selected the nodes that appear in the mapping, the table at the top of the Mapping page should reflect the mapping you have defined.

Generating transformation files

Once you define the mapping, you can generate the transformation files that are used to convert XML documents to data packets and to convert data packets to XML documents. Note that only the transformation file is directional: a single mapping can be used to generate both the transformation from XML to data packet and from data packet to XML.

To generate a transformation file

1. First select the radio button that indicates what the transformation creates:
   - Choose the Datapacket to XML button if the mapping goes from data packet to XML document.
   - Choose the XML to Datapacket button if the mapping goes from XML document to data packet.
2. If you are generating a data packet, you will also want to use the radio buttons in the Create Datapacket As section. These buttons let you specify how the data packet will be used: as a dataset, as a delta packet for applying updates, or as the parameters to supply to a provider before fetching data.
3. Click Create and Test Transformation to generate an in-memory version of the transformation. XML mapper displays the XML document that would be generated for the data packet in the Datapacket pane or the data packet that would be generated for the XML document in the XML Document pane.
4. Finally, choose **File ▸ Save ▸ Transformation** to save the transformation file. The transformation file is a special XML file (with the .xtr extension) that describes the transformation you have defined.

Mapping Between XML Nodes and Data Packet Fields (see page 1843)

3.2.3.14 Working with field components

Topics

Name	Description
Accessing Field Values with a Dataset's FieldByName Method (see page 1853)	You can access the value of a field with a dataset's FieldByName method. This method is useful when you know the name of the field you want to access, but do not have access to the underlying table at design time. To use *FieldByName*, you must know the dataset and name of the field you want to access. You pass the field's name as an argument to the method. To access or change the field's value, convert the result with the appropriate field component conversion property, such as *AsString* or *AsInteger*. For example, the following statement assigns the... more (see page 1853)

Accessing Field Values with a Dataset's Fields Property (see page 1854)	You can access the value of a field with the Fields property of the dataset component to which the field belongs. *Fields* maintains an indexed list of all the fields in the dataset. Accessing field values with the *Fields* property is useful when you need to iterate over a number of columns, or if your application works with tables that are not available to you at design time. To use the *Fields* property you must know the order of and data types of fields in the dataset. You use an ordinal number to specify the field to access. The first... more (see page 1854)
Arranging Persistent Fields (see page 1854)	The order in which persistent field components are listed in the Fields editor list box is the default order in which the fields appear in a data-aware grid component. You can change field order by dragging and dropping fields in the list box.
Associating Attribute Sets with Field Components (see page 1854)	When several fields in the datasets used by your application share common formatting properties (such as *Alignment*, *DisplayWidth*, *DisplayFormat*, *EditFormat*, *MaxValue*, *MinValue*, and so on), and you have saved those property settings as attribute sets in the Data Dictionary, you can easily apply the attribute sets to fields without having to recreate the settings manually for each field. In addition, if you later change the attribute settings in the Data Dictionary, those changes are automatically applied to every field associated with the set the next time field components are added to the dataset.
Creating a Custom Constraint (see page 1855)	A custom constraint is not imported from the server like other constraints. It is a constraint that you declare, implement, and enforce in your local application. As such, custom constraints can be useful for offering a prevalidation enforcement of data entry, but a custom constraint cannot be applied against data received from or sent to a server application. To create a custom constraint, set the *CustomConstraint* property to specify a constraint condition, and set *ConstraintErrorMessage* to the message to display when a user violates the constraint at runtime. *CustomConstraint* is an SQL string that specifies any application-specific constraints imposed on... more (see page 1855)
Defining a Data Field (see page 1855)	A data field replaces an existing field in a dataset. For example, for programmatic reasons you might want to replace a TSmallIntField with a TIntegerField. Because you cannot change a field's data type directly, you must define a new field to replace it. **Warning:** Even though you define a new field to replace an existing field, the field you define must derive its data values from an existing column in a table underlying a dataset.
Defining an Aggregate Field (see page 1856)	An aggregate field displays values from a maintained aggregate in a client dataset. An aggregate is a calculation that summarizes the data in a set of records. See Using maintained aggregates (see page 1735) for details about maintained aggregates.
Defining New Persistent Fields (see page 1856)	Besides making existing dataset fields into persistent fields, you can also create special persistent fields as additions to or replacements of the other persistent fields in a dataset. New persistent fields that you create are only for display purposes. The data they contain at runtime are not retained either because they already exist elsewhere in the database, or because they are temporary. The physical structure of the data underlying the dataset is not changed in any way. To create a new persistent field component, invoke the context menu for the Fields editor by right clicking and choose New field. The... more (see page 1856)
Deleting Persistent Field Components (see page 1857)	Deleting a persistent field component is useful for accessing a subset of available columns in a table, and for defining your own persistent fields to replace a column in a table.
Displaying, Converting, and Accessing Field Values (see page 1858)	Data-aware controls such as TDBEdit and TDBGrid automatically display the values associated with field components. If editing is enabled for the dataset and the controls, data-aware controls can also send new and changed values to the database. In general, the built-in properties and methods of data-aware controls enable them to connect to datasets, display values, and make updates without requiring extra programming on your part. Use them whenever possible in your database applications. For more information about data-aware control, see Using data controls (see page 1778). Standard controls can also display and edit database values associated with field components. Using standard controls,... more (see page 1858)
Displaying Field Component Values in Standard Controls (see page 1858)	An application can access the value of a dataset column through the *Value* property of a field component. For example, the following *OnDataChange* event handler updates the text in a TEdit control because the value of the *CustomersCompany* field may have changed:

Persistent Field Components (see page 1859)	By default, dataset fields are dynamic. Their properties and availability are automatically set and cannot be changed in any way. To gain control over a field's properties and events you must create persistent fields for the dataset. Persistent fields let you • Set or change the field's display or edit characteristics at design time or runtime. • Create new fields, such as lookup fields, calculated fields, and aggregated fields, that base their values on existing fields in a dataset. • Validate data entry. • Remove field components from the list of persistent components to prevent your application from accessing particular columns in an underlying... more (see page 1859)
Removing Attribute Associations (see page 1860)	If you change your mind about associating an attribute set with a field, you can remove the association.
Setting a Default Value for a Field (see page 1860)	You can specify how a default value for a field in a client dataset or a BDE-enabled dataset should be calculated at runtime using the DefaultExpression property. *DefaultExpression* can be any valid SQL value expression that does not refer to field values. If the expression contains literals other than numeric values, they must appear in quotes. For example, a default value of noon for a time field would be
Setting Display and Edit Properties at Design Time (see page 1860)	To edit the display properties of a selected field component, switch to the Properties page on the **Object Inspector** window. The following table summarizes display properties that can be edited. ***Field component properties***
Using Object Fields (see page 1862)	Object fields are fields that represent a composite of other, simpler datatypes. These include ADT (Abstract Data Type) fields, Array fields, DataSet fields, and Reference fields. All of these field types either contain or reference child fields or other data sets. ADT fields and array fields are fields that contain child fields. The child fields of an ADT field can be any scalar or object type (that is, any other field type). These child fields may differ in type from each other. An array field contains an array of child fields, all of the same type. Dataset and reference fields... more (see page 1862)
Using Server Constraints (see page 1863)	Most production SQL databases use constraints to impose conditions on the possible values for a field. For example, a field may not permit NULL values, may require that its value be unique for that column, or that its values be greater than *0* and less than *150*. While you could replicate such conditions in your client applications, client datasets and BDE-enabled datasets offer the *ImportedConstraint* property to propagate a server's constraints locally. *ImportedConstraint* is a read-only property that specifies an SQL clause that limits field values in some manner. For example:
Working with Constraints (see page 1863)	Field components in client datasets or BDE-enabled datasets can use SQL server constraints (see page 1863). In addition, your applications can create and use custom constraints (see page 1855) for these datasets that are local to your application. All constraints are rules or conditions that impose a limit on the scope or range of values that a field can store.
Working with Field Component Methods at Runtime (see page 1864)	Field components methods available at runtime enable you to convert field values from one data type to another, and enable you to set focus to the first data-aware control in a form that is associated with a field component. Controlling the focus of data-aware components associated with a field is important when your application performs record-oriented data validation in a dataset event handler (such as BeforePost). Validation may be performed on the fields in a record whether or not its associated data-aware control has focus. Should validation fail for a particular field in the record, you want the data-aware control... more (see page 1864)
Working with ADT Fields (see page 1864)	ADTs are user-defined types created on the server, and are similar to the record type. An ADT can contain most scalar field types, array fields, reference fields, and nested ADTs. There are a variety of ways to access the data in ADT field types. These are illustrated in the following examples, which assign a child field value to an edit box called CityEdit, and use the following ADT structure,

Working with Array Fields (see page 1866)	Array fields consist of a set of fields of the same type. The field types can be scalar (for example, float, string), or non-scalar (an ADT), but an array field of arrays is not permitted. The SparseArrays property of *TDataSet* determines whether a unique TField object is created for each element of the array field. There are a variety of ways to access the data in array field types. If you are not using persistent fields, the dataset's ObjectView property must be set to True before you can access the elements of an array field.
Working with DataSet Fields (see page 1867)	Dataset fields provide access to data stored in a nested dataset. The NestedDataSet property references the nested dataset. The data in the nested dataset is then accessed through the field objects of the nested dataset.
Working with Reference Fields (see page 1867)	Reference fields store a pointer or reference to another ADT object. This ADT object is a single record of another object table. Reference fields always refer to a single record in a dataset (object table). The data in the referenced object is actually returned in a nested dataset, but can also be accessed via the Fields property on the *TReferenceField*.
Defining a Lookup Field (see page 1868)	A lookup field is a read-only field that displays values at runtime based on search criteria you specify. In its simplest form, a lookup field is passed the name of an existing field to search on, a field value to search for, and a different field in a lookup dataset whose value it should display. For example, consider a mail-order application that enables an operator to use a lookup field to determine automatically the city and state that correspond to the zip code a customer provides. The column to search on might be called *ZipTable.Zip*, the value to search... more (see page 1868)
Creating Attribute Sets for Field Components (see page 1870)	When several fields in the datasets used by your application share common formatting properties (such as *Alignment*, *DisplayWidth*, *DisplayFormat*, *EditFormat*, *MaxValue*, *MinValue*, and so on), it is more convenient to set the properties for a single field, then store those properties as an attribute set in the Data Dictionary. Attribute sets stored in the data dictionary can be easily applied to other fields. **Note:** Attribute sets and the Data Dictionary are only available for BDE-enabled datasets.
Programming a Calculated Field (see page 1870)	After you define a calculated field, you must write code to calculate its value. Otherwise, it always has a null value. Code for a calculated field is placed in the *OnCalcFields* event for its dataset.
Setting Persistent Field Properties and Events (see page 1871)	You can set properties and customize events for persistent field components at design time. Properties control the way a field is displayed by a data-aware component, for example, whether it can appear in a TDBGrid, or whether its value can be modified. Events control what happens when data in a field is fetched, changed, set, or validated. To set the properties of a field component or write customized event handlers for it, select the component in the Fields editor, or select it from the component list in the **Object Inspector**. The following topics discuss using persistent field properties and... more (see page 1871)
Handling Events (see page 1871)	Like most components, field components have events associated with them. Methods can be assigned as handlers for these events. By writing these handlers you can react to the occurrence of events that affect data entered in fields through data-aware controls and perform actions of your own design. The following table lists the events associated with field components: ***Field component events***
Accessing Field Values with the Default Dataset Property (see page 1872)	The most general method for accessing a field's value is to use Variants with the *FieldValues* property. For example, the following statement puts the value of an edit box into the *CustNo* field in the *Customers* table:
Defining a Calculated Field (see page 1872)	A calculated field displays values calculated at runtime by a dataset's OnCalcFields event handler. For example, you might create a string field that displays concatenated values from other fields.
Using Default Formatting for Numeric, Date, and Time Fields (see page 1873)	Delphi provides built-in display and edit format routines and intelligent default formatting for TFloatField, TCurrencyField, TBCDField, TFMTBCDField, TIntegerField, TSmallIntField, TWordField, TDateField, TDateTimeField, TTimeField, and TSQLTimeStampField components. To use these routines, you need do nothing. Default formatting is performed by the following routines: ***Field component formatting routines***
Setting Field Component Properties at Runtime (see page 1873)	You can use and manipulate the properties of field component at runtime. Access persistent field components by name, where the name can be obtained by concatenating the field name to the dataset name. For example, the following code sets the *ReadOnly* property for the *CityStateZip* field in the *Customers* table to *True*:

Creating Persistent Fields (see page 1874)	Persistent field components created with the Fields editor provide efficient, readable, and type-safe programmatic access to underlying data. Using persistent field components guarantees that each time your application runs, it always uses and displays the same columns, in the same order even if the physical structure of the underlying database has changed. Data-aware components and program code that rely on specific fields always work as expected. If a column on which a persistent field component is based is deleted or changed, Delphi generates an exception rather than running the application against a nonexistent column or mismatched data.
Converting Field Values (see page 1874)	Conversion properties attempt to convert one data type to another. For example, the *AsString* property converts numeric and Boolean values to string representations. The following table lists field component conversion properties, and which properties are recommended for field components by field-component class:
Dynamic Field Components (see page 1876)	Dynamically generated field components are the default. In fact, all field components for any dataset start out as dynamic fields the first time you place a dataset on a data module, specify how that dataset fetches its data, and open it. A field component is *dynamic* if it is created automatically based on the underlying physical characteristics of the data represented by a dataset. Datasets generate one field component for each column in the underlying data. The exact TField descendant created for each column is determined by field type information received from the database or (for *TClientDataSet*) from a... more (see page 1876)
Working with Field Components: Overview (see page 1877)	Field components represent individual fields (columns) in datasets. You can use field components to control the display and editing of data in your applications. Field components are always associated with a dataset. You never use a TField object directly in your applications. Instead, each field component in your application is a *TField* descendant specific to the datatype of a column in a dataset. Field components provide data-aware controls such as TDBEdit and TDBGrid access to the data in a particular column of the associated dataset. Generally speaking, a single field component represents the characteristics of a single column, or field,... more (see page 1877)
Controlling and Masking User Input (see page 1878)	The *EditMask* property provides a way to control the type and range of values a user can enter into a data-aware component associated with TStringField, TDateField, TTimeField, and TDateTimeField, and TSQLTimeStampField components. You can use existing masks or create your own. The easiest way to use and create edit masks is with the Input Mask editor. You can, however, enter masks directly into the *EditMask* field in the **Object Inspector**. **Note:** For *TStringField* components, the *EditMask* property is also its display format.

3.2.3.14.1 Accessing Field Values with a Dataset's FieldByName Method

You can access the value of a field with a dataset's FieldByName method. This method is useful when you know the name of the field you want to access, but do not have access to the underlying table at design time.

To use *FieldByName*, you must know the dataset and name of the field you want to access. You pass the field's name as an argument to the method. To access or change the field's value, convert the result with the appropriate field component conversion property, such as *AsString* or *AsInteger*. For example, the following statement assigns the value of the *CustNo* field in the *Customers* dataset to an edit control:

```
Edit2.Text := Customers.FieldByName('CustNo').AsString;
Edit2->Text = Customers->FieldByName("CustNo")->AsString;
```

Conversely, you can assign a value to a field:

```
begin
  Customers.Edit;
  Customers.FieldByName('CustNo').AsString := Edit2.Text;
  Customers.Post;
end;
Customers->Edit();
Customers->FieldByName("CustNo")->AsString = Edit2->Text;
Customers->Post();
```

Displaying Field Component Values in Standard Controls (see page 1858)

Accessing Field Values with a Dataset's Fields Property (see page 1854)

3.2.3.14.2 Accessing Field Values with a Dataset's Fields Property

You can access the value of a field with the Fields property of the dataset component to which the field belongs. *Fields* maintains an indexed list of all the fields in the dataset. Accessing field values with the *Fields* property is useful when you need to iterate over a number of columns, or if your application works with tables that are not available to you at design time.

To use the *Fields* property you must know the order of and data types of fields in the dataset. You use an ordinal number to specify the field to access. The first field in a dataset is numbered 0. Field values must be converted as appropriate using each field component's conversion properties (see page 1874).

For example, the following statement assigns the current value of the seventh column (Country) in the *Customers* table to an edit control:

```
Edit1.Text := CustTable.Fields[6].AsString;
Edit1->Text = CustTable->Fields->Fields[6]->AsString;
```

Conversely, you can assign a value to a field by setting the *Fields* property of the dataset to the desired field. For example:

```
begin
  Customers.Edit;
  Customers.Fields[6].AsString := Edit1.Text;
  Customers.Post;
end;
Customers->Edit();
Customers->Insert();
Customers->Fields->Fields[6]->AsString = Edit1->Text;
Customers->Post();
```

Accessing Field Values with a Dataset's FieldByName Method (see page 1853)

3.2.3.14.3 Arranging Persistent Fields

The order in which persistent field components are listed in the Fields editor list box is the default order in which the fields appear in a data-aware grid component. You can change field order by dragging and dropping fields in the list box.

To change the order of fields

1. Select the fields. You can select and order one or more fields at a time.
2. Drag the fields to a new location.

If you select a noncontiguous set of fields and drag them to a new location, they are inserted as a contiguous block. Within the block, the order of fields does not change.

Alternatively, you can select the field, and use `Ctrl+Up` and `Ctrl+Dn` to change an individual field's order in the list.

See Also

Defining New Persistent Fields (see page 1856)

Deleting Persistent Field Components (see page 1857)

3.2.3.14.4 Associating Attribute Sets with Field Components

When several fields in the datasets used by your application share common formatting properties (such as *Alignment*,

DisplayWidth, *DisplayFormat*, *EditFormat*, *MaxValue*, *MinValue*, and so on), and you have saved those property settings as attribute sets in the Data Dictionary, you can easily apply the attribute sets to fields without having to recreate the settings manually for each field. In addition, if you later change the attribute settings in the Data Dictionary, those changes are automatically applied to every field associated with the set the next time field components are added to the dataset.

To apply an attribute set to a field component

1. Double-click the dataset to invoke the Fields editor.
2. Select the field for which to apply an attribute set.
3. Invoke the context menu and choose Associate Attributes.
4. Select or enter the attribute set to apply from the Associate Attributes dialog box. If there is an attribute set in the Data Dictionary that has the same name as the current field, that set name appears in the edit box.

   Warning: If the attribute set in the Data Dictionary is changed at a later date, you must reapply the attribute set to each field component that uses it. You can invoke the Fields editor and multi-select field components within a dataset when reapplying attributes.

See Also

Removing Attribute Associations (see page 1860)

The Data Dictionary (see page 1680)

3.2.3.14.5 Creating a Custom Constraint

A custom constraint is not imported from the server like other constraints. It is a constraint that you declare, implement, and enforce in your local application. As such, custom constraints can be useful for offering a prevalidation enforcement of data entry, but a custom constraint cannot be applied against data received from or sent to a server application.

To create a custom constraint, set the *CustomConstraint* property to specify a constraint condition, and set *ConstraintErrorMessage* to the message to display when a user violates the constraint at runtime.

CustomConstraint is an SQL string that specifies any application-specific constraints imposed on the field's value. Set *CustomConstraint* to limit the values that the user can enter into a field. *CustomConstraint* can be any valid SQL search expression such as

```
x > 0 and x < 100
```

The name used to refer to the value of the field can be any string that is not a reserved SQL keyword, as long as it is used consistently throughout the constraint expression.

Note: Custom constraints are only available in BDE-enabled and client datasets.

Custom constraints are imposed in addition to any constraints to the field's value that come from the server. To see the constraints imposed by the server, read the *ImportedConstraint* property.

See Also

Using Server Constraints (see page 1863)

3.2.3.14.6 Defining a Data Field

A data field replaces an existing field in a dataset. For example, for programmatic reasons you might want to replace a TSmallIntField with a TIntegerField. Because you cannot change a field's data type directly, you must define a new field to replace it.

Warning: Even though you define a new field to replace an existing field, the field you define must derive its data values from an existing column in a table underlying a dataset.

To create a replacement data field for a field in a table underlying a dataset

1. Remove the field from the list of persistent fields assigned for the dataset, and then choose New Field from the context menu.
2. In the New Field dialog box, enter the name of an existing field in the database table in the Name edit box. Do not enter a new field name. You are actually specifying the name of the field from which your new field will derive its data.
3. Choose a new data type for the field from the Type combo box. The data type you choose should be different from the data type of the field you are replacing. You cannot replace a string field of one size with a string field of another size. Note that while the data type should be different, it must be compatible with the actual data type of the field in the underlying table.
4. Enter the size of the field in the Size edit box, if appropriate. Size is only relevant for fields of type TStringField, TBytesField, and TVarBytesField.
5. Select Data in the Field type radio group if it is not already selected.
6. Choose OK. The New Field dialog box closes, the newly defined data field replaces the existing field you specified in Step 1, and the component declaration in the data module or form's **type** declaration is updated.

To edit the properties or events associated with the field component, select the component name in the Field editor list box, then edit its properties or events with the **Object Inspector**. For more information about editing field component properties and events, see Setting persistent field properties and events (see page 1871).

See Also

Defining a Calculated Field (see page 1872)

Creating an Aggregate Field (see page 1856)

3.2.3.14.7 Defining an Aggregate Field

An aggregate field displays values from a maintained aggregate in a client dataset. An aggregate is a calculation that summarizes the data in a set of records. See Using maintained aggregates (see page 1735) for details about maintained aggregates.

To create an aggregate field in the New Field dialog box

1. Enter a name for the aggregate field in the Name edit box. Do not enter the name of an existing field.
2. Choose aggregate data type for the field from the Type combo box.
3. Select Aggregate in the Field type radio group.
4. Choose OK. The newly defined aggregate field is automatically added to the client dataset and its Aggregates property is automatically updated to include the appropriate aggregate specification.
5. Place the calculation for the aggregate in the *ExprText* property of the newly created aggregate field. For more information about defining an aggregate, see Specifying aggregates (see page 1730).

Once a persistent *TAggregateField* is created, a *TDBText* control can be bound to the aggregate field. The *TDBText* control will then display the value of the aggregate field that is relevant to the current record of the underlying client data set.

See Also

Defining a Data Field (see page 1855)

Defining a Calculated Field (see page 1872)

3.2.3.14.8 Defining New Persistent Fields

Besides making existing dataset fields into persistent fields, you can also create special persistent fields as additions to or replacements of the other persistent fields in a dataset.

New persistent fields that you create are only for display purposes. The data they contain at runtime are not retained either

because they already exist elsewhere in the database, or because they are temporary. The physical structure of the data underlying the dataset is not changed in any way.

To create a new persistent field component, invoke the context menu for the Fields editor by right clicking and choose New field. The New Field dialog box appears.

The New Field dialog box contains three group boxes: Field properties, Field type, and Lookup definition.

- The Field properties group box lets you enter general field component information. Enter the field name in the Name edit box. The name you enter here corresponds to the field component's *FieldName property. The New Field dialog uses this name to build a component name in the Component edit box. The name that appears in the Component edit box corresponds to the field component's Name property and is only provided for informational purposes (Name is the identifier by which you refer to the field component in your source code). The dialog discards anything you enter directly in the Component edit box.*
- The Type combo box in the Field properties group lets you specify the field component's data type. You must supply a data type for any new field component you create. For example, to display floating-point currency values in a field, select *Currency* from the drop-down list. Use the Size edit box to specify the maximum number of characters that can be displayed or entered in a string-based field, or the size of *Bytes* and *VarBytes* fields. For all other data types, Size is meaningless.
- The Field type radio group lets you specify the type of new field component to create. The default type is Data. If you choose Lookup, the Dataset and Source Fields edit boxes in the Lookup definition group box are enabled. You can also create Calculated fields, and if you are working with a client dataset, you can create InternalCalc fields or Aggregate fields. The following table describes these types of fields you can create:

Special persistent field kinds

Field Kind	Purpose
Data	Replaces an existing field (for example to change its data type)
Calculated	Displays values calculated at runtime by a dataset's *OnCalcFields* event handler.
Lookup	Retrieve values from a specified dataset at runtime based on search criteria you specify. (not supported by unidirectional datasets)
InternalCalc	Displays values calculated at runtime by a client dataset and stored with its data.
Aggregate	Displays a value summarizing the data in a set of records from a client dataset.

The Lookup definition group box is only used to create lookup fields. This is described more fully in Defining a lookup field (see page 1868).

The following topics describe how to create different field types:

- Defining a Data Field (see page 1855)
- Defining a Calculated Field (see page 1872)
- Defining a Lookup Field (see page 1868)
- Defining an Aggregate Field (see page 1856)

See Also

Arranging Persistent Fields (see page 1854)

Deleting Persistent Field Components (see page 1857)

3.2.3.14.9 Deleting Persistent Field Components

Deleting a persistent field component is useful for accessing a subset of available columns in a table, and for defining your own persistent fields to replace a column in a table.

To remove one or more persistent field components for a dataset

1. Select the field(s) to remove in the Fields editor list box.

2. Press Del.

   Note: You can also delete selected fields by invoking the context menu and choosing Delete.

   Fields you remove are no longer available to the dataset and cannot be displayed by data-aware controls. You can always recreate a persistent field component that you delete by accident, but any changes previously made to its properties or events is lost. For more information, see Creating persistent fields (see page 1874)

   Note: If you remove all persistent field components for a dataset, the dataset reverts to using dynamic field components for every column in the underlying database table.

See Also

Arranging Persistent Fields (see page 1854)

Defining New Persistent Fields (see page 1856)

3.2.3.14.10 Displaying, Converting, and Accessing Field Values

Data-aware controls such as TDBEdit and TDBGrid automatically display the values associated with field components. If editing is enabled for the dataset and the controls, data-aware controls can also send new and changed values to the database. In general, the built-in properties and methods of data-aware controls enable them to connect to datasets, display values, and make updates without requiring extra programming on your part. Use them whenever possible in your database applications. For more information about data-aware control, see Using data controls (see page 1778).

Standard controls can also display and edit database values associated with field components. Using standard controls, however, may require additional programming on your part. For example, when using standard controls, your application is responsible for tracking when to update controls because field values change. If the dataset has a datasource component, you can use its events to help you do this. In particular, the OnDataChange event lets you know when you may need to update a control's value and the OnStateChange event can help you determine when to enable or disable controls. For more information on these events, see Responding to changes mediated by the data source (see page 1776).

The following topics discuss how to work with field values so that you can display them in standard controls:

- Displaying Field Component Values in Standard Controls (see page 1858)
- Converting Field Values (see page 1874)
- Accessing Field Values with the Default Dataset Property (see page 1872)
- Accessing Field Values with a Dataset's Fields Property (see page 1854)
- Accessing Field Values with a Dataset's FieldByName Method (see page 1853)

Working with Constraints (see page 1863)

Using Object Fields (see page 1862)

3.2.3.14.11 Displaying Field Component Values in Standard Controls

An application can access the value of a dataset column through the *Value* property of a field component. For example, the following *OnDataChange* event handler updates the text in a TEdit control because the value of the *CustomersCompany* field may have changed:

```
procedure TForm1.CustomersDataChange(Sender: TObject, Field: TField);
```

```
begin
  Edit3.Text := CustomersCompany.Value;
end;
void __fastcall TForm1::Table1DataChange(TObject *Sender, TField *Field)
{
  Edit3->Text = CustomersCompany->Value;
}
```

This method works well for string values, but may require additional programming to handle conversions for other data types. Fortunately, field components have built-in properties for handling conversions (see page 1874).

Note: You can also use Variants to access and set field values (see page 1872).

Accessing Field Values with a Dataset's Fields Property (see page 1854)

Accessing Field Values with a Dataset's FieldByName Method (see page 1853)

3.2.3.14.12 Persistent Field Components

By default, dataset fields are dynamic. Their properties and availability are automatically set and cannot be changed in any way. To gain control over a field's properties and events you must create persistent fields for the dataset. Persistent fields let you

- Set or change the field's display or edit characteristics at design time or runtime.
- Create new fields, such as lookup fields, calculated fields, and aggregated fields, that base their values on existing fields in a dataset.
- Validate data entry.
- Remove field components from the list of persistent components to prevent your application from accessing particular columns in an underlying database.
- Define new fields to replace existing fields, based on columns in the table or query underlying a dataset.

At design time, you can—and should—use the Fields editor to create persistent lists of the field components used by the datasets in your application. Persistent field component lists are stored in your application, and do not change even if the structure of a database underlying a dataset is changed. Once you create persistent fields with the Fields editor, you can also create event handlers for them that respond to changes in data values and that validate data entries.

Note: When you create persistent fields for a dataset, only those fields you select are available to your application at design time and runtime. At design time, you can always use the Fields editor to add or remove persistent fields for a dataset.

All fields used by a single dataset are either persistent or dynamic. You cannot mix field types in a single dataset. If you create persistent fields for a dataset, and then want to revert to dynamic fields, you must remove all persistent fields from the dataset. For more information about dynamic fields, see Dynamic field components (see page 1876).

Note: One of the primary uses of persistent fields is to gain control over the appearance and display of data. You can also control the appearance of columns in data-aware grids. To learn about controlling column appearance in grids, see Creating a customized grid (see page 1754).

The following topics describe how to use the Fields editor to create or modify the persistent fields in a dataset, and how to work with persistent fields:

- Creating Persistent Fields (see page 1874)
- Arranging Persistent Fields (see page 1854)
- Defining New Persistent Fields (see page 1856)
- Deleting Persistent Field Components (see page 1857)
- Setting Persistent Field Properties and Events (see page 1871)

Using Object Fields (see page 1862)

3.2.3.14.13 Removing Attribute Associations

If you change your mind about associating an attribute set with a field, you can remove the association.

To remove an attribute association

1. Invoke the Fields editor for the dataset containing the field.
2. Select the field or fields from which to remove the attribute association.
3. Invoke the context menu for the Fields editor and choose Unassociate Attributes.

   Warning: Unassociating an attribute set does not change any field properties. A field retains the settings it had when the attribute set was applied to it. To change these properties, select the field in the Fields editor and set its properties in the Object Inspector

   .

See Also

Associating Attribute Sets with Field Components (see page 1854)

The Data Dictionary (see page 1680)

3.2.3.14.14 Setting a Default Value for a Field

You can specify how a default value for a field in a client dataset or a BDE-enabled dataset should be calculated at runtime using the DefaultExpression property. *DefaultExpression* can be any valid SQL value expression that does not refer to field values. If the expression contains literals other than numeric values, they must appear in quotes. For example, a default value of noon for a time field would be

```
'12:00:00'
```

including the quotes around the literal value.

Note: If the underlying database table defines a default value for the field, the default you specify in *DefaultExpression* takes precedence. That is because *DefaultExpression* is applied when the dataset posts the record containing the field, before the edited record is applied to the database server.

Persistent Field Components (see page 1859)

Working with Constraints (see page 1863)

Using Object Fields (see page 1862)

3.2.3.14.15 Setting Display and Edit Properties at Design Time

To edit the display properties of a selected field component, switch to the Properties page on the **Object Inspector** window. The

following table summarizes display properties that can be edited.

Field component properties

Property	Purpose
Alignment	Left justifies, right justifies, or centers a field contents within a data-aware component.
ConstraintErrorMessage	Specifies the text to display when edits clash with a constraint condition.
CustomConstraint	Specifies a local constraint to apply to data during editing.
Currency	Numeric fields only. *True*: displays monetary values.False (default): does not display monetary values.
DisplayFormat	Specifies the format of data displayed in a data-aware component.
DisplayLabel	Specifies the column name for a field in a data-aware grid component.
DisplayWidth	Specifies the width, in characters, of a grid column that display this field.
EditFormat	Specifies the edit format of data in a data-aware component.
EditMask	Limits data-entry in an editable field to specified types and ranges of characters, and specifies any special, non-editable characters that appear within the field (hyphens, parentheses, and so on).
FieldKind	Specifies the type of field to create.
FieldName	Specifies the actual name of a column in the table from which the field derives its value and data type.
HasConstraints	Indicates whether there are constraint conditions imposed on a field.
ImportedConstraint	Specifies an SQL constraint imported from the Data Dictionary or an SQL server.
Index	Specifies the order of the field in a dataset.
LookupDataSet	Specifies the table used to look up field values when *Lookup* is *True*.
LookupKeyFields	Specifies the field(s) in the lookup dataset to match when doing a lookup.
LookupResultField	Specifies the field in the lookup dataset from which to copy values into this field.
MaxValue	Numeric fields only. Specifies the maximum value a user can enter for the field.
MinValue	Numeric fields only. Specifies the minimum value a user can enter for the field.
Name	Specifies the component name of the field component within Delphi.
Origin	Specifies the name of the field as it appears in the underlying database.
Precision	Numeric fields only. Specifies the number of significant digits.
ReadOnly	*True*: Displays field values in data-aware controls, but prevents editing. *False* (the default): Permits display and editing of field values.
Size	Specifies the maximum number of characters that can be displayed or entered in a string-based field, or the size, in bytes, of *TBytesField* and *TVarBytesField* fields.
Tag	Long integer bucket available for programmer use in every component as needed.
Transliterate	*True* (default): specifies that translation to and from the respective locales will occur as data is transferred between a dataset and a database. *False*: Locale translation does not occur.
Visible	*True* (the default): Permits display of field in a data-aware grid.False: Prevents display of field in a data-aware grid component.User-defined components can make display decisions based on this property.

Not all properties are available for all field components. For example, a field component of type TStringField does not have *Currency*, *MaxValue*, or *DisplayFormat* properties, and a component of type TFloatField does not have a *Size* property.

While the purpose of most properties is straightforward, some properties, such as Calculated, require additional programming

steps to be useful. Others, such as *DisplayFormat*, *EditFormat*, and *EditMask*, are interrelated; their settings must be coordinated. For more information about using *DisplayFormat*, *EditFormat*, and *EditMask*, see Controlling and masking user input (see page 1878).

3.2.3.14.16 Using Object Fields

Object fields are fields that represent a composite of other, simpler datatypes. These include ADT (Abstract Data Type) fields, Array fields, DataSet fields, and Reference fields. All of these field types either contain or reference child fields or other data sets.

ADT fields and array fields are fields that contain child fields. The child fields of an ADT field can be any scalar or object type (that is, any other field type). These child fields may differ in type from each other. An array field contains an array of child fields, all of the same type.

Dataset and reference fields are fields that access other data sets. A dataset field provides access to a nested (detail) dataset and a reference field stores a pointer (reference) to another persistent object (ADT).

Types of object field components

Component Name	Purpose
TADTField	Represents an ADT (Abstract Data Type) field.
TArrayField	Represents an array field.
TDataSetField	Represents a field that contains a nested data set reference.
TReferenceField	Represents a REF field, a pointer to an ADT.

When you add fields with the Fields editor to a dataset that contains object fields, persistent object fields of the correct type are automatically created for you. Adding persistent object fields to a dataset automatically sets the dataset's ObjectView property to *True*, which instructs the dataset to store these fields hierarchically, rather than flattening them out as if the constituent child fields were separate, independent fields.

The following properties are common to all object fields and provide the functionality to handle child fields and datasets.

Common object field descendant properties

Property	Purpose
Fields	Contains the child fields belonging to the object field.
ObjectType	Classifies the object field.
FieldCount	Number of child fields belonging to the object field.
FieldValues	Provides access to the values of the child fields.

Displaying ADT and array fields

Both ADT and array fields contain child fields that can be displayed through data-aware controls.

Data-aware controls such as TDBEdit that represent a single field value display child field values in an uneditable comma delimited string. In addition, if you set the control's *DataField* property to the child field instead of the object field itself, the child field can be viewed an edited just like any other normal data field.

A TDBGrid control displays ADT and array field data differently, depending on the value of the dataset's ObjectView property. When *ObjectView* is *False*, each child field appears in a single column. When *ObjectView* is *True*, an ADT or array field can be expanded and collapsed by clicking on the arrow in the title bar of the column. When the field is expanded, each child field appears in its own column and title bar, all below the title bar of the ADT or array itself. When the ADT or array is collapsed, only one column appears with an uneditable comma-delimited string containing the child fields.

The following topics discuss each type of object field in more detail:

- Working with ADT Fields (see page 1864)
- Working with Array Fields (see page 1866)
- Working with Dataset Fields (see page 1867)
- Working with Reference Fields (see page 1867)

Displaying (see page 1858)

Setting a Default Value for a Field (see page 1860)

Working with Constraints (see page 1863)

Persistent Field Components (see page 1859)

3.2.3.14.17 Using Server Constraints

Most production SQL databases use constraints to impose conditions on the possible values for a field. For example, a field may not permit NULL values, may require that its value be unique for that column, or that its values be greater than *0* and less than *150*. While you could replicate such conditions in your client applications, client datasets and BDE-enabled datasets offer the *ImportedConstraint* property to propagate a server's constraints locally.

ImportedConstraint is a read-only property that specifies an SQL clause that limits field values in some manner. For example:

```
Value > 0 and Value < 100
```

Do not change the value of *ImportedConstraint*, except to edit nonstandard or server-specific SQL that has been imported as a comment because it cannot be interpreted by the database engine.

To add additional constraints on the field value, use the *CustomConstraint* property. Custom constraints are imposed in addition to the imported constraints. If the server constraints change, the value of *ImportedConstraint* also changed but constraints introduced in the *CustomConstraint* property persist.

Removing constraints from the *ImportedConstraint* property will not change the validity of field values that violate those constraints. Removing constraints results in the constraints being checked by the server instead of locally. When constraints are checked locally, the error message supplied as the *ConstraintErrorMessage* property is displayed when violations are found, instead of displaying an error message from the server.

See Also

Creating a Custom Constraint (see page 1855)

3.2.3.14.18 Working with Constraints

Field components in client datasets or BDE-enabled datasets can use SQL server constraints (see page 1863). In addition, your applications can create and use custom constraints (see page 1855) for these datasets that are local to your application. All constraints are rules or conditions that impose a limit on the scope or range of values that a field can store.

Displaying (see page 1858)

Setting a Default Value for a Field (see page 1860)

Persistent Field Components (see page 1859)

Using Object Fields (see page 1862)

3.2.3.14.19 Working with Field Component Methods at Runtime

Field components methods available at runtime enable you to convert field values from one data type to another, and enable you to set focus to the first data-aware control in a form that is associated with a field component.

Controlling the focus of data-aware components associated with a field is important when your application performs record-oriented data validation in a dataset event handler (such as BeforePost). Validation may be performed on the fields in a record whether or not its associated data-aware control has focus. Should validation fail for a particular field in the record, you want the data-aware control containing the faulty data to have focus so that the user can enter corrections.

You control focus for a field's data-aware components with a field's FocusControl method. *FocusControl* sets focus to the first data-aware control in a form that is associated with a field. An event handler should call a field's *FocusControl* method before validating the field. The following code illustrates how to call the *FocusControl* method for the *Company* field in the *Customers* table:

```
CustomersCompany.FocusControl;
CustomersCompany->FocusControl();
```

The following table lists some other field component methods and their uses. For a complete list and detailed information about using each method, see TField.

Selected field component methods

Method	Purpose
AssignValue	Sets a field value to a specified value using an automatic conversion function based on the field's type.
Clear	Clears the field and sets its value to NULL.
GetData	Retrieves unformatted data from the field.
IsValidChar	Determines if a character entered by a user in a data-aware control to set a value is allowed for this field.
SetData	Assigns unformatted data to this field.

3.2.3.14.20 Working with ADT Fields

ADTs are user-defined types created on the server, and are similar to the record type. An ADT can contain most scalar field types, array fields, reference fields, and nested ADTs.

There are a variety of ways to access the data in ADT field types. These are illustrated in the following examples, which assign a child field value to an edit box called CityEdit, and use the following ADT structure,

```
Address
  Street
  City
```

```
  State
  Zip
```

Using persistent field components

The easiest way to access ADT field values is to use persistent field components. For the ADT structure above, the following persistent fields can be added to the Customer table using the Fields editor:

```
CustomerAddress: TADTField;
CustomerAddrStreet: TStringField;
CustomerAddrCity: TStringField;
CustomerAddrState: TStringField;
CustomerAddrZip: TStringField;
```

Given these persistent fields, you can simply access the child fields of an ADT field by name:

```
CityEdit.Text := CustomerAddrCity.AsString;
CityEdit->Text = CustomerAddrCity->AsString;
```

Although persistent fields are the easiest way to access ADT child fields, it is not possible to use them if the structure of the dataset is not known at design time. When accessing ADT child fields without using persistent fields, you must set the dataset's ObjectView property to True.

Using the dataset's FieldByName method

You can access the children of an ADT field using the dataset's FieldByName method by qualifying the name of the child field with the ADT field's name:

```
CityEdit.Text := Customer.FieldByName('Address.City').AsString;
```

Using the dateset's FieldValues property

You can also use qualified field names with a dataset's *FieldValues* property:

```
CityEdit.Text := Customer['Address.City'];
CityEdit->Text = Customer->FieldValues["Address.City"];
```

Note that you can omit the property name (*FieldValues*) because *FieldValues* is the dataset's default property.

Note: Unlike other runtime methods for accessing ADT child field values, the *FieldValues* property works even if the dataset's *ObjectView* property is False.

Using the ADT field's FieldValues property

You can access the value of a child field with the TADTField's FieldValues property. FieldValues accepts and returns a Variant, so it can handle and convert fields of any type. The index parameter is an integer value that specifies the offset of the field.

```
CityEdit.Text := TADTField(Customer.FieldByName('Address')).FieldValues[1];
CityEdit->Text = ((TADTField*)Customer->FieldByName("Address"))->FieldValues[1];
```

Because FieldValues is the default property of TADTField, the property name (FieldValues) can be omitted. Thus, the following statement is equivalent to the one above:

```
CityEdit.Text := TADTField(Customer.FieldByName('Address'))[1];
```

Using the ADT field's Fields property

Each ADT field has a Fields property that is analogous to the *Fields* property of a dataset. Like the *Fields* property of a dataset, you can use it to access child fields by position:

```
CityEdit.Text := TADTField(Customer.FieldByName('Address')).Fields[1].AsString;
CityEdit->Text = ((TADTField*)Customer->FieldByName("Address"))->Fields->
```

or by name:

```
CityEdit.Text :=
TADTField(Customer.FieldByName('Address')).Fields.FieldByName('City').AsString;
CityEdit->Text = ((TADTField*)Customer->FieldByName("Address"))->
CityEdit->Text = Customer->FieldByName("Address.City")->AsString;
```

Working with Array Fields (see page 1866)

Working with DataSet Fields (see page 1867)

Working with Reference Fields (see page 1867)

3.2.3.14.21 Working with Array Fields

Array fields consist of a set of fields of the same type. The field types can be scalar (for example, float, string), or non-scalar (an ADT), but an array field of arrays is not permitted. The SparseArrays property of *TDataSet* determines whether a unique TField object is created for each element of the array field.

There are a variety of ways to access the data in array field types. If you are not using persistent fields, the dataset's ObjectView property must be set to True before you can access the elements of an array field.

Using persistent fields

You can map persistent fields to the individual array elements in an array field. For example, consider an array field *TelNos_Array*, which is a six element array of strings. The following persistent fields created for the Customer table component represent the *TelNos_Array* field and its six elements:

```
CustomerTelNos_Array: TArrayField;
CustomerTelNos_Array0: TStringField;
CustomerTelNos_Array1: TStringField;
CustomerTelNos_Array2: TStringField;
CustomerTelNos_Array3: TStringField;
CustomerTelNos_Array4: TStringField;
CustomerTelNos_Array5: TStringField;
CustomerTELNOS_ARRAY: TArrayField;
CustomerTELNOS_ARRAY0: TStringField;
CustomerTELNOS_ARRAY1: TStringField;
CustomerTELNOS_ARRAY2: TStringField;
CustomerTELNOS_ARRAY3: TStringField;
CustomerTELNOS_ARRAY4: TStringField;
CustomerTELNOS_ARRAY5: TStringField;
```

Given these persistent fields, the following code uses a persistent field to assign an array element value to an edit box named *TelEdit*.

```
TelEdit.Text := CustomerTelNos_Array0.AsString;
TelEdit->Text = CustomerTELNOS_ARRAY0->AsString;
```

Using the array field's FieldValues property

You can access the value of a child field with the array field's *FieldValues* property. *FieldValues* accepts and returns a *Variant*, so it can handle and convert child fields of any type. For example,

```
TelEdit.Text := TArrayField(Customer.FieldByName('TelNos_Array')).FieldValues[1];
TelEdit->Text = ((TArrayField*)Customer->FieldByName("TelNos_Array"))->FieldValues[1];
```

Because *FieldValues* is the default property of *TArrayField*, this can also be written

```
TelEdit.Text := TArrayField(Customer.FieldByName('TelNos_Array'))[1];
```

Using the array field's Fields property

TArrayField has a Fields property that you can use to access individual sub-fields. This is illustrated below, where an array field (*OrderDates*) is used to populate a list box with all non-null array elements:

```
for I := 0 to OrderDates.Size - 1 do
begin
  if not OrderDates.Fields[I].IsNull then
    OrderDateListBox.Items.Add(OrderDates[I]);
```

```
end;
for (int i = 0; i < OrderDates->Size; ++i)
  if (!OrderDates->Fields->Fields[i]->IsNull)
    OrderDateListBox->Items->Add(OrderDates->Fields->Fields[i]->AsString);
```

Working with ADT Fields (see page 1864)

Working with DataSet Fields (see page 1867)

Working with Reference Fields (see page 1867)

3.2.3.14.22 Working with DataSet Fields

Dataset fields provide access to data stored in a nested dataset. The NestedDataSet property references the nested dataset. The data in the nested dataset is then accessed through the field objects of the nested dataset.

Displaying dataset fields

TDBGrid controls enable the display of data stored in data set fields. In a TDBGrid control, a dataset field is indicated in each cell of a dataset column with the string "(DataSet)", and at runtime an ellipsis button also exists to the right. Clicking on the ellipsis brings up a new form with a grid displaying the dataset associated with the current record's dataset field. This form can also be brought up programmatically with the DB grid's ShowPopupEditor method. For example, if the seventh column in the grid represents a dataset field, the following code will display the dataset associated with that field for the current record.

```
DBGrid1.ShowPopupEditor(DBGrid1.Columns[7]);
DBGrid1->ShowPopupEditor(DBGrid1->Columns->Items[7], -1, -1);
```

Accessing data in a nested dataset

A dataset field is not normally bound directly to a data aware control. Rather, since a nested data set is just that, a data set, the means to get at its data is via a *TDataSet* descendant. The type of dataset you use is determined by the parent dataset (the one with the dataset field.) For example, a BDE-enabled dataset uses *TNestedTable* to represent the data in its dataset fields, while client datasets use other client datasets.

To access the data in a dataset field

1. Create a persistent TDataSetField object by invoking the Fields editor for the parent dataset.
2. Create a dataset to represent the values in that dataset field. It must be of a type compatible with the parent dataset.
3. Set that DataSetField property of the dataset created in step 2 to the persistent dataset field you created in step 1.

If the nested dataset field for the current record has a value, the detail dataset component will contain records with the nested data; otherwise, the detail dataset will be empty.

Before inserting records into a nested dataset, you should be sure to post the corresponding record in the master table, if it has just been inserted. If the inserted record is not posted, it will be automatically posted before the nested dataset posts.

See Also

Working with ADT Fields (see page 1864)

Working with Array Fields (see page 1866)

Working with Reference Fields (see page 1867)

3.2.3.14.23 Working with Reference Fields

Reference fields store a pointer or reference to another ADT object. This ADT object is a single record of another object table. Reference fields always refer to a single record in a dataset (object table). The data in the referenced object is actually returned in a nested dataset, but can also be accessed via the Fields property on the *TReferenceField*.

Displaying reference fields

In a TDBGrid control a reference field is designated in each cell of the dataset column, with (Reference) and, at runtime, an ellipsis button to the right. At runtime, clicking on the ellipsis brings up a new form with a grid displaying the object associated with the current record's reference field.

This form can also be brought up programmatically with the DB grid's ShowPopupEditor method. For example, if the seventh column in the grid represents a reference field, the following code will display the object associated with that field for the current record.

```
DBGrid1.ShowPopupEditor(DBGrid1.Columns[7]);
DBGrid1->ShowPopupEditor(DBGrid1->Columns->Items[7], -1, -1);
```

Accessing data in a reference field

You can access the data in a reference field in the same way you access a nested dataset.

To access data in a reference field

1. Create a persistent TDataSetField object by invoking the Fields editor for the parent dataset.
2. Create a dataset to represent the value of that dataset field.
3. Set that DataSetField property of the dataset created in step 2 to the persistent dataset field you created in step 1.

If the reference is assigned, the reference dataset will contain a single record with the referenced data. If the reference is null, the reference dataset will be empty.

You can also use the reference field's Fields property to access the data in a reference field. For example, the following lines are equivalent and assign data from the reference field *CustomerRefCity* to an edit box called *CityEdit*:

```
CityEdit.Text := CustomerRefCity.Fields[1].AsString;
CityEdit.Text := CustomerRefCity.NestedDataSet.Fields[1].AsString;
CityEdit->Text = CustomerADDRESS_REF->NestedDataSet->Fields->Fields[1]->AsString;
```

When data in a reference field is edited, it is actually the referenced data that is modified.

To assign a reference field, you need to first use a SELECT statement to select the reference from the table, and then assign. For example:

```
var
  AddressQuery: TQuery;
  CustomerAddressRef: TReferenceField;
begin
  AddressQuery.SQL.Text := 'SELECT REF(A) FROM AddressTable A WHERE A.City = ''San
Francisco''';
  AddressQuery.Open;
  CustomerAddressRef.Assign(AddressQuery.Fields[0]);
end;
AddressQuery->SQL->Text = "SELECT REF(A) FROM AddressTable A WHERE A.City = "San Francisco"";
AddressQuery->Open();
CustomerAddressRef->Assign(AddressQuery->Fields->Fields[0]);
```

Working with DataSet Fields (see page 1867)

3.2.3.14.24 Defining a Lookup Field

A lookup field is a read-only field that displays values at runtime based on search criteria you specify. In its simplest form, a lookup field is passed the name of an existing field to search on, a field value to search for, and a different field in a lookup

dataset whose value it should display.

For example, consider a mail-order application that enables an operator to use a lookup field to determine automatically the city and state that correspond to the zip code a customer provides. The column to search on might be called *ZipTable.Zip*, the value to search for is the customer's zip code as entered in *Order.CustZip*, and the values to return would be those for the *ZipTable.City* and *ZipTable.State* columns of the record where the value of *ZipTable.Zip* matches the current value in the *Order.CustZip* field.

Note: Unidirectional datasets do not support lookup fields.

To create a lookup field in the New Field dialog box

1. Enter a name for the lookup field in the Name edit box. Do not enter the name of an existing field.
2. Choose a data type for the field from the Type combo box.
3. Enter the size of the field in the Size edit box, if appropriate. Size is only relevant for fields of type TStringField, TBytesField, and TVarBytesField.
4. Select Lookup in the Field type radio group. Selecting Lookup enables the Dataset and Key Fields combo boxes.
5. Choose from the Dataset combo box drop-down list the dataset in which to look up field values. The lookup dataset must be different from the dataset for the field component itself, or a circular reference exception is raised at runtime. Specifying a lookup dataset enables the Lookup Keys and Result Field combo boxes.
6. Choose from the Key Fields drop-down list a field in the current dataset for which to match values. To match more than one field, enter field names directly instead of choosing from the drop-down list. Separate multiple field names with semicolons. If you are using more than one field, you must use persistent field components.
7. Choose from the Lookup Keys drop-down list a field in the lookup dataset to match against the Source Fields field you specified in step 6. If you specified more than one key field, you must specify the same number of lookup keys. To specify more than one field, enter field names directly, separating multiple field names with semicolons.
8. Choose from the Result Field drop-down list a field in the lookup dataset to return as the value of the lookup field you are creating.

When you design and run your application, lookup field values are determined before calculated field values are calculated. You can base calculated fields on lookup fields, but you cannot base lookup fields on calculated fields.

You can use the LookupCache property to hone the way lookup fields are determined. *LookupCache* determines whether the values of a lookup field are cached in memory when a dataset is first opened, or looked up dynamically every time the current record in the dataset changes. Set *LookupCache* to *True* to cache the values of a lookup field when the LookupDataSet is unlikely to change and the number of distinct lookup values is small. Caching lookup values can speed performance, because the lookup values for every set of *LookupKeyFields values are preloaded when the DataSet is opened. When the current record in the DataSet changes, the field object can locate its Value in the cache, rather than accessing the LookupDataSet. This performance improvement is especially dramatic if the LookupDataSet is on a network where access is slow.*

If every record of DataSet has different values for KeyFields, the overhead of locating values in the cache can be greater than any performance benefit provided by the cache. The overhead of locating values in the cache increases with the number of distinct values that can be taken by KeyFields.

If LookupDataSet is volatile, caching lookup values can lead to inaccurate results. Call RefreshLookupList to update the values in the lookup cache. RefreshLookupList regenerates the LookupList property, which contains the value of the LookupResultField for every set of LookupKeyFields values.

When setting LookupCache at runtime, call RefreshLookupList to initialize the cache.

Defining a Data Field (see page 1855)

Defining a Calculated Field (see page 1872)

Creating an Aggregate Field (see page 1856)

3.2.3.14.25 Creating Attribute Sets for Field Components

When several fields in the datasets used by your application share common formatting properties (such as *Alignment*, *DisplayWidth*, *DisplayFormat*, *EditFormat*, *MaxValue*, *MinValue*, and so on), it is more convenient to set the properties for a single field, then store those properties as an attribute set in the Data Dictionary. Attribute sets stored in the data dictionary can be easily applied to other fields.

Note: Attribute sets and the Data Dictionary are only available for BDE-enabled datasets.

To create an attribute set based on a field component in a dataset

1. Double-click the dataset to invoke the Fields editor.
2. Select the field for which to set properties.
3. Set the desired properties for the field in the **Object Inspector**.
4. Right-click the Fields editor list box to invoke the context menu.
5. Choose Save Attributes to save the current field's property settings as an attribute set in the Data Dictionary.

The name for the attribute set defaults to the name of the current field. You can specify a different name for the attribute set by choosing Save Attributes As instead of Save Attributes from the context menu.

Once you have created a new attribute set and added it to the Data Dictionary, you can then associate it with other persistent field components (see page 1854). Even if you later remove the association (see page 1860), the attribute set remains defined in the Data Dictionary.

See Also

Setting Display and Edit Properties at Design Time (see page 1860)

Associating Attribute Sets with Field Components (see page 1854)

Removing Attribute Associations (see page 1860)

The Data Dictionary (see page 1680)

3.2.3.14.26 Programming a Calculated Field

After you define a calculated field, you must write code to calculate its value. Otherwise, it always has a null value. Code for a calculated field is placed in the *OnCalcFields* event for its dataset.

To program a value for a calculated field

1. Select the dataset component from the **Object Inspector** drop-down list.
2. Choose the **Object Inspector** Events page.
3. Double-click the OnCalcFields property to bring up or create a CalcFields procedure for the dataset component.
4. Write the code that sets the values and other properties of the calculated field as desired.

For example, suppose you have created a *CityStateZip* calculated field for the *Customers* table on the *CustomerData* data module. *CityStateZip* should display a company's city, state, and zip code on a single line in a data-aware control.

To add code to the *CalcFields* procedure for the *Customers* table, select the *Customers* table from the **Object Inspector** drop-down list, switch to the Events page, and double-click the *OnCalcFields* property.

The *TCustomerData.CustomersCalcFields* procedure appears in the unit's source code window. Add the following code to the procedure to calculate the field:

```
CustomersCityStateZip.Value := CustomersCity.Value + ', ' + CustomersState.Value  + ' ' +
CustomersZip.Value;
CustomersCityStateZip->Value = CustomersCity->Value + AnsiString(", ") +
```

Note: When writing the *OnCalcFields* event handler for an internally calculated field, you can improve performance by checking the client dataset's State property and only recomputing the value when *State* is *dsInternalCalc*. See Using internally calculated fields in client datasets (see page 1735) for details.

See Also

Defining a Calculated Field (see page 1872)

3.2.3.14.27 Setting Persistent Field Properties and Events

You can set properties and customize events for persistent field components at design time. Properties control the way a field is displayed by a data-aware component, for example, whether it can appear in a TDBGrid, or whether its value can be modified. Events control what happens when data in a field is fetched, changed, set, or validated.

To set the properties of a field component or write customized event handlers for it, select the component in the Fields editor, or select it from the component list in the **Object Inspector**.

The following topics discuss using persistent field properties and events:

- Setting Display and Edit Properties at Design Time (see page 1860)
- Setting Field Component Properties at Runtime (see page 1873)
- Creating Attribute Sets for Field Components (see page 1870)
- Controlling and Masking User Input (see page 1878)
- Using Default Formatting for Numeric (see page 1873)
- Handling Events (see page 1871)

See Also

Arranging Persistent Fields (see page 1854)

Defining New Persistent Fields (see page 1856)

Deleting Persistent Field Components (see page 1857)

3.2.3.14.28 Handling Events

Like most components, field components have events associated with them. Methods can be assigned as handlers for these events. By writing these handlers you can react to the occurrence of events that affect data entered in fields through data-aware controls and perform actions of your own design. The following table lists the events associated with field components:

Field component events

Event	Purpose
OnChange	Called when the value for a field changes.
OnGetText	Called when the value for a field component is retrieved for display or editing.
OnSetText	Called when the value for a field component is set.
OnValidate	Called to validate the value for a field component whenever the value is changed because of an edit or insert operation.

OnGetText and OnSetText events are primarily useful to programmers who want to do custom formatting that goes beyond the built-in formatting functions. *OnChange* is useful for performing application-specific tasks associated with data change, such as enabling or disabling menus or visual controls. OnValidate is useful when you want to control data-entry validation in your application before returning values to a database server.

To write an event handler for a field component

1. Select the component.
2. Select the Events page in the **Object Inspector**.
3. Double-click the Value field for the event handler to display its source code window.
4. Create or edit the handler code.

See Also

Setting Display and Edit Properties at Design Time (see page 1860)

3.2.3.14.29 Accessing Field Values with the Default Dataset Property

The most general method for accessing a field's value is to use Variants with the *FieldValues* property. For example, the following statement puts the value of an edit box into the *CustNo* field in the *Customers* table:

```
Customers.FieldValues['CustNo'] := Edit2.Text;
Customers->FieldValues["CustNo"] = Edit2->Text;
```

Because the *FieldValues* property is of type *Variant*, it automatically converts other datatypes into a *Variant* value.

See Also

Displaying Field Component Values in Standard Controls (see page 1858)

Accessing Field Values with a Dataset's Fields Property (see page 1854)

Accessing Field Values with a Dataset's FieldByName Method (see page 1853)

3.2.3.14.30 Defining a Calculated Field

A calculated field displays values calculated at runtime by a dataset's OnCalcFields event handler. For example, you might create a string field that displays concatenated values from other fields.

To create a calculated field in the New Field dialog box

1. Enter a name for the calculated field in the Name edit box. Do not enter the name of an existing field.
2. Choose a data type for the field from the Type combo box.
3. Enter the size of the field in the Size edit box, if appropriate. Size is only relevant for fields of type TStringField, TBytesField, and TVarBytesField.
4. Select Calculated or InternalCalc in the Field type radio group. InternalCalc is only available if you are working with a client dataset. The significant difference between these types of calculated fields is that the values calculated for an InternalCalc field are stored and retrieved as part of the client dataset's data.
5. Choose OK. The newly defined calculated field is automatically added to the end of the list of persistent fields in the Field editor list box, and the component declaration is automatically added to the form's or data module's **type** declaration.
6. Place code that calculates values for the field in the OnCalcFields event handler for the dataset. For more information about writing code to calculate field values, see Programming a calculated field (see page 1870).

   Note: To edit the properties or events associated with the field component, select the component name in the Field editor list box, then edit its properties or events with the Object Inspector

   . For more information about editing field component properties and events, see Setting persistent field properties and events (see page 1871).

Programming a Calculated Field (see page 1870)

3.2.3.14.31 Using Default Formatting for Numeric, Date, and Time Fields

Delphi provides built-in display and edit format routines and intelligent default formatting for TFloatField, TCurrencyField, TBCDField, TFMTBCDField, TIntegerField, TSmallIntField, TWordField, TDateField, TDateTimeField, TTimeField, and TSQLTimeStampField components. To use these routines, you need do nothing.

Default formatting is performed by the following routines:

Field component formatting routines

Routine	Used by . . .
FormatFloat	*TFloatField*, *TCurrencyField*
FormatDateTime	*TDateField*, *TTimeField*, *TDateTimeField*,
SQLTimeStampToString	*TSQLTimeStampField*
FormatCurr	*TCurrencyField, TBCDField*
BcdToStrF	TFMTBCDField

Only format properties appropriate to the data type of a field component are available for a given component.

Default formatting conventions for date, time, currency, and numeric values are based on the Regional Settings properties in the Control Panel. For example, using the default settings for the United States, a *TFloatField* column with the *Currency* property set to *True* sets the *DisplayFormat* property for the value 1234.56 to $1234.56, while the EditFormat is 1234.56.

At design time or runtime, you can edit the *DisplayFormat* and EditFormat properties of a field component to override the default display settings for that field. You can also write *OnGetText and OnSetText event handlers to do custom formatting for field components at runtime.*

See Also

Setting Display and Edit Properties at Design Time (see page 1860)

3.2.3.14.32 Setting Field Component Properties at Runtime

You can use and manipulate the properties of field component at runtime. Access persistent field components by name, where the name can be obtained by concatenating the field name to the dataset name.

For example, the following code sets the *ReadOnly* property for the *CityStateZip* field in the *Customers* table to *True*:

```
CustomersCityStateZip.ReadOnly := True;
CustomersCityStateZip->ReadOnly = true;
```

And this statement changes field ordering by setting the Index property of the *CityStateZip* field in the *Customers* table to 3:

```
CustomersCityStateZip.Index := 3;
CustomersCityStateZip->Index = 3;
```

Setting Display and Edit Properties at Design Time (see page 1860)

3.2.3.14.33 Creating Persistent Fields

Persistent field components created with the Fields editor provide efficient, readable, and type-safe programmatic access to underlying data. Using persistent field components guarantees that each time your application runs, it always uses and displays the same columns, in the same order even if the physical structure of the underlying database has changed. Data-aware components and program code that rely on specific fields always work as expected. If a column on which a persistent field component is based is deleted or changed, Delphi generates an exception rather than running the application against a nonexistent column or mismatched data.

To create persistent fields for a dataset

1. Place a dataset in a data module.
2. Bind the dataset to its underlying data. This typically involves associating the dataset with a connection component or provider and specifying any properties to describe the data. For example, If you are using *TADODataSet*, you can set the *Connection* property to a properly configured *TADOConnection* component and set the *CommandText* property to a valid query.
3. Double-click the dataset component in the data module to invoke the Fields editor. The Fields editor contains a title bar, navigator buttons, and a list box. The title bar of the Fields editor displays both the name of the data module or form containing the dataset, and the name of the dataset itself. For example, if you open the *Customers* dataset in the *CustomerData* data module, the title bar displays 'CustomerData.Customers,' or as much of the name as fits. Below the title bar is a set of navigation buttons that let you scroll one-by-one through the records in an active dataset at design time, and to jump to the first or last record. The navigation buttons are dimmed if the dataset is not active or if the dataset is empty. If the dataset is unidirectional, the buttons for moving to the last record and the previous record are always dimmed. The list box displays the names of persistent field components for the dataset. The first time you invoke the Fields editor for a new dataset, the list is empty because the field components for the dataset are dynamic, not persistent. If you invoke the Fields editor for a dataset that already has persistent field components, you see the field component names in the list box.
4. Right click in the Fields editor and choose Add Fields.
5. Select the fields to make persistent in the Add Fields dialog box. By default, all fields are selected when the dialog box opens. Any fields you select become persistent fields.

The Add Fields dialog box closes, and the fields you selected appear in the Fields editor list box. Fields in the Fields editor list box are persistent. If the dataset is active, note, too, that the Next and (if the dataset is not unidirectional) Last navigation buttons above the list box are enabled.

From now on, each time you open the dataset, it no longer creates dynamic field components for every column in the underlying database. Instead it only creates persistent components for the fields you specified.

Each time you open the dataset, it verifies that each non-calculated persistent field exists or can be created from data in the database. If it cannot, the dataset raises an exception warning you that the field is not valid, and does not open the dataset.

Deleting Persistent Field Components (see page 1857)

3.2.3.14.34 Converting Field Values

Conversion properties attempt to convert one data type to another. For example, the *AsString* property converts numeric and Boolean values to string representations. The following table lists field component conversion properties, and which properties are recommended for field components by field-component class:

Field Components	AsVariant	AsString	AsInteger	AsFloat, AsCurrency, AsBCD	AsDateTime, AsSQLTimeStamp	AsBoolean
TStringField	yes	NA	yes	yes	yes	yes
TWideStringField	yes	yes	yes	yes	yes	yes
TIntegerField	yes	yes	NA	yes		
TSmallIntField	yes	yes	yes	yes		
TWordField	yes	yes	yes	yes		
TLargeintField	yes	yes	yes	yes		
TFloatField	yes	yes	yes	yes		
TCurrencyField	yes	yes	yes	yes		
TBCDField	yes	yes	yes	yes		
TFMTBCDField	yes	yes	yes	yes		
TDateTimeField	yes	yes		yes	yes	
TDateField	yes	yes		yes	yes	
TTimeField	yes	yes		yes	yes	
TSQLTimeStampField	yes	yes		yes	yes	
TBooleanField	yes	yes				
TBytesField	yes	yes				
TVarBytesField	yes	yes				
TBlobField	yes	yes				
TMemoField	yes	yes				
TGraphicField	yes	yes				
TVariantField	NA	yes	yes	yes	yes	yes
TAggregateField	yes	yes				

Note that some columns in the table refer to more than one conversion property (such as *AsFloat*, *AsCurrency*, and *AsBCD*). This is because all field data types that support one of those properties always support the others as well.

Note also that the *AsVariant* property can translate among all data types. For any datatypes not listed above, *AsVariant* is also available (and is, in fact, the only option). When in doubt, use *AsVariant*.

In some cases, conversions are not always possible. For example, *AsDateTime* can be used to convert a string to a date, time, or datetime format only if the string value is in a recognizable datetime format. A failed conversion attempt raises an exception.

In some other cases, conversion is possible, but the results of the conversion are not always intuitive. For example, what does it mean to convert a TDateTimeField value into a float format? *AsFloat* converts the date portion of the field to the number of days since 12/31/1899, and it converts the time portion of the field to a fraction of 24 hours. The following table lists permissible conversions that produce special results:

Special conversion results

Conversion	Result
String to Boolean	Converts "True," "False," "Yes," and "No" to Boolean. Other values raise exceptions.
Float to Integer	Rounds float value to nearest integer value.

DateTime or SQLTimeStamp to Float	Converts date to number of days since 12/31/1899, time to a fraction of 24 hours.
Boolean to String	Converts any Boolean value to "True" or "False."

In other cases, conversions are not possible at all. In these cases, attempting a conversion also raises an exception.

Conversion always occurs before an assignment is made. For example, the following statement converts the value of *CustomersCustNo* to a string and assigns the string to the text of an edit control:

```
Edit1.Text := CustomersCustNo.AsString;
Edit1->Text = CustomersCustNo->AsString;
```

Conversely, the next statement assigns the text of an edit control to the *CustomersCustNo* field as an integer:

```
MyTableMyField.AsInteger := StrToInt(Edit1.Text);
MyTableMyField->AsInteger = StrToInt(Edit1->Text);
```

3.2.3.14.35 Dynamic Field Components

Dynamically generated field components are the default. In fact, all field components for any dataset start out as dynamic fields the first time you place a dataset on a data module, specify how that dataset fetches its data, and open it. A field component is *dynamic* if it is created automatically based on the underlying physical characteristics of the data represented by a dataset. Datasets generate one field component for each column in the underlying data. The exact TField descendant created for each column is determined by field type information received from the database or (for *TClientDataSet*) from a provider component.

Dynamic fields are temporary. They exist only as long as a dataset is open. Each time you reopen a dataset that uses dynamic fields, it rebuilds a completely new set of dynamic field components based on the current structure of the data underlying the dataset. If the columns in the underlying data change, then the next time you open a dataset that uses dynamic field components, the automatically generated field components are also changed to match.

Use dynamic fields in applications that must be flexible about data display and editing. For example, to create a database browsing tool you must use dynamic fields because every database table has different numbers and types of columns. You might also want to use dynamic fields in applications where user interaction with data mostly takes place inside grid components and you know that the datasets used by the application change frequently.

To use dynamic fields in an application

1. Place datasets and data sources in a data module.
2. Associate the datasets with data. This involves using a connection component or provider to connect to the source of the data and setting any properties that specify what data the dataset represents.
3. Associate the data sources with the datasets.
4. Place data-aware controls in the application's forms, add the data module to each uses clause for each form's unit, and associate each data-aware control with a data source in the module. In addition, associate a field with each data-aware control that requires one. Note that because you are using dynamic field components, there is no guarantee that any field name you specify will exist when the dataset is opened.
5. Open the datasets.

Aside from ease of use, dynamic fields can be limiting. Without writing code, you cannot change the display and editing defaults for dynamic fields, you cannot safely change the order in which dynamic fields are displayed, and you cannot prevent access

to any fields in the dataset. You cannot create additional fields for the dataset, such as calculated fields or lookup fields, and you cannot override a dynamic field's default data type. To gain control and flexibility over fields in your database applications, you need to invoke the Fields editor to create persistent field components for your datasets.

3.2.3.14.36 Working with Field Components: Overview

Field components represent individual fields (columns) in datasets. You can use field components to control the display and editing of data in your applications.

Field components are always associated with a dataset. You never use a TField object directly in your applications. Instead, each field component in your application is a *TField* descendant specific to the datatype of a column in a dataset. Field components provide data-aware controls such as TDBEdit and TDBGrid access to the data in a particular column of the associated dataset.

Generally speaking, a single field component represents the characteristics of a single column, or field, in a dataset, such as its data type and size. It also represents the field's display characteristics, such as alignment, display format, and edit format. For example, a TFloatField component has four properties that directly affect the appearance of its data:

TFloatField properties that affect data display

Property	Purpose
Alignment	Specifies whether data is displayed left-aligned, centered, or right-aligned.
DisplayWidth	Specifies the number of digits to display in a control at one time.
DisplayFormat	Specifies data formatting for display (such as how many decimal places to show).
EditFormat	Specifies how to display a value during editing.

As you scroll from record to record in a dataset, a field component lets you view and change the value for that field in the current record.

Field components have many properties in common with one another (such as DisplayWidth and *Alignment*), and they have properties specific to their data types (such as Precision for *TFloatField*). Each of these properties affect how data appears to an application's users on a form. Some properties, such as *Precision*, can also affect what data values the user can enter in a control when modifying or entering data.

All field components for a dataset are either *dynamic* (automatically generated for you based on the underlying structure of database tables), or *persistent* (generated based on specific field names and properties you set in the Fields editor). Dynamic and persistent fields have different strengths and are appropriate for different types of applications.

The following topics discuss field components in greater detail:

- Dynamic Field Components (see page 1876)
- Persistent Field Components (see page 1859)
- Working with Field Component Methods at Runtime (see page 1864)

- Displaying (see page 1858)
- Setting a Default Value for a Field (see page 1860)
- Working with Constraints (see page 1863)
- Using Object Fields (see page 1862)

3.2.3.14.37 Controlling and Masking User Input

The *EditMask* property provides a way to control the type and range of values a user can enter into a data-aware component associated with TStringField, TDateField, TTimeField, and TDateTimeField, and TSQLTimeStampField components. You can use existing masks or create your own. The easiest way to use and create edit masks is with the Input Mask editor. You can, however, enter masks directly into the *EditMask* field in the **Object Inspector**.

Note: For *TStringField* components, the *EditMask* property is also its display format.

To invoke the Input Mask editor for a field component

1. Select the component in the Fields editor or **Object Inspector**.
2. Click the Properties page in the **Object Inspector**.
3. Double-click the values column for the EditMask field in the **Object Inspector**, or click the ellipsis button. The Input Mask editor opens.

The Input Mask edit box lets you create and edit a mask format. The Sample Masks grid lets you select from predefined masks. If you select a sample mask, the mask format appears in the Input Mask edit box where you can modify it or use it as is. You can test the allowable user input for a mask in the Test Input edit box.

The Masks button enables you to load a custom set of masks—if you have created one—into the Sample Masks grid for easy selection.

3.2.4.1.1 Creating packages and DLLs

Topics

Name	Description
Creating DLLs Containing VCL Components (C++) (see page 1880)	One of the strengths of DLLs is that a DLL created with one development tool can often be used by application written using a different development tool. When your DLL contains VCL components (such as forms) that are to be used by the calling application, you need to provide exported interface routines that use standard calling conventions, avoid C++ name mangling, and do not require the calling application to support the VCL libraries in order to work. To create VCL components that can be exported, use runtime packages. For example, suppose you want to create a DLL to display the... more (see page 1880)
Creating Packages and DLLs (see page 1882)	Dynamic link libraries (DLLs) are modules of compiled code that work in conjunction with an executable to provide functionality to an application. You can create DLLs in cross-platform programs. However, on Linux, DLLs (and packages) recompile as shared objects. DLLs and libraries should handle all exceptions to prevent the display of errors and warnings through Windows dialogs. The following compiler directives can be placed in library project files: ***Compiler directives for libraries***
Linking DLLs (see page 1883)	You can set the linker options for your DLL on the Linker page of the **Project Options** dialog box. The default check box on this page also creates an import library for your DLL. If compiling from the command line, invoke the linker, `ilink32.exe`, with the `-Tpd` switch. For example:
When to Use Packages and DLLs (see page 1883)	For most applications, packages provide greater flexibility and are easier to create than DLLs. However, there are several situations where DLLs would be better suited to your projects than packages: • Your code module will be called from non-Delphi applications. • You are extending the functionality of a Web server. • You are creating a code module to be used by third-party developers. • Your project is an OLE container. You cannot pass Delphi runtime type information (RTTI) across DLLs or from a DLL to an executable. If you pass an object from one DLL to another DLL or an executable, you will not... more (see page 1883)
Using DLLs in RAD Studio (C++) (see page 1883)	A Windows DLL can be used in a RAD Studio application just as it would be in any C++ application. To statically load a DLL when your C++ application is loaded, link the import library file for that DLL into your C++ application at link time. To add an import library to a C++ application, choose Project->Add to Project and select the `.lib` file you want to add to the libraries to be linked. The exported functions of that DLL then become available for use by your application. Prototype the DLL functions your application uses with the __declspec (dllimport) modifier:... more (see page 1883)

3.2.4.1.1.1 Creating DLLs Containing VCL Components (C++)

One of the strengths of DLLs is that a DLL created with one development tool can often be used by application written using a different development tool. When your DLL contains VCL components (such as forms) that are to be used by the calling application, you need to provide exported interface routines that use standard calling conventions, avoid C++ name mangling, and do not require the calling application to support the VCL libraries in order to work. To create VCL components that can be exported, use runtime packages.

For example, suppose you want to create a DLL to display the following simple dialog box:

The code for the dialog box DLL is as follows:

```
// DLLMAIN.H
//---------------------------------------------------------------------------
#ifndef dllMainH
#define dllMainH
//---------------------------------------------------------------------------
#include <Classes.hpp>
#include <vcl\Controls.hpp>
#include <vcl\StdCtrls.hpp>
#include <vcl\Forms.hpp>
//---------------------------------------------------------------------------
class TYesNoDialog : public TForm
{
    __published:    // IDE-managed Components
        TLabel *LabelText;
        TButton *YesButton;
        TButton *NoButton;
        void __fastcall YesButtonClick(TObject *Sender);
        void __fastcall NoButtonClick(TObject *Sender);
    private:        // User declarations
        bool returnValue;
    public:         // User declarations
        virtual __fastcall TYesNoDialog(TComponent *Owner);
        bool __fastcall GetReturnValue();
};
// exported interface function
extern "C" __declspec(dllexport) bool InvokeYesNoDialog();
//---------------------------------------------------------------------------
extern TYesNoDialog *YesNoDialog;
//---------------------------------------------------------------------------
#endif
// DLLMAIN.CPP
//---------------------------------------------------------------------------
#include <vcl\vcl.h>
#pragma hdrstop
#include "dllMain.h"
//---------------------------------------------------------------------------
#pragma resource "*.dfm"
TYesNoDialog *YesNoDialog;
//---------------------------------------------------------------------------
__fastcall TYesNoDialog::TYesNoDialog(TComponent *Owner)
    : TForm(Owner)
{
    returnValue = false;
}
//---------------------------------------------------------------------------
void __fastcall TYesNoDialog::YesButtonClick(TObject *Sender)
{
    returnValue = true;
    Close();
}
//---------------------------------------------------------------------------
void __fastcall TYesNoDialog::NoButtonClick(TObject *Sender)
{
    returnValue = false;
    Close();
}
//---------------------------------------------------------------------------
```

```
bool __fastcall TYesNoDialog::GetReturnValue()
{
    return returnValue;
}
//---------------------------------------------------------------------------
// exported standard C++ interface function that calls into VCL
bool InvokeYesNoDialog()
{
    bool returnValue;
    TYesNoDialog *YesNoDialog = new TYesNoDialog(NULL);
    YesNoDialog->ShowModal();
    returnValue = YesNoDialog->GetReturnValue();
    delete YesNoDialog;
    return returnValue;
}
//---------------------------------------------------------------------------
```

The code in this example displays the dialog and stores the value true in the private data member `returnValue` if the "Yes" button is pressed. Otherwise, `returnValue` is **false**. The public `GetReturnValue()` function retrieves the current value of `returnValue`.

To invoke the dialog and determine which button was pressed, the calling application calls the exported function `InvokeYesNoDialog()`. This function is declared in DLLMAIN.H as an exported function using C linkage (to avoid C++ name mangling) and the standard C calling convention. The function is defined in `DLLMAIN.CPP`.

By using a standard C function as the interface into the DLL, any calling application, whether or not it was created with RAD Studio, can use the DLL. The VCL functionality required to support the dialog is linked into the DLL itself, and the calling application does not need to know anything about it.

Note: When creating a DLL that uses the VCL, the required VCL components are linked into the DLL resulting in a certain amount of overhead. The impact of this overhead on the overall size of the application can be minimized by combining several components into one DLL that only needs one copy of the VCL support components.

3.2.4.1.1.2 Creating Packages and DLLs

Dynamic link libraries (DLLs) are modules of compiled code that work in conjunction with an executable to provide functionality to an application. You can create DLLs in cross-platform programs. However, on Linux, DLLs (and packages) recompile as shared objects.

DLLs and libraries should handle all exceptions to prevent the display of errors and warnings through Windows dialogs.

The following compiler directives can be placed in library project files:

Compiler directives for libraries

Compiler Directive	Description
{$LIBPREFIX 'string'}	Adds a specified prefix to the output file name. For example, you could specify {$LIBPREFIX 'dcl'} for a design-time package, or use {$LIBPREFIX''} to eliminate the prefix entirely.
{$LIBSUFFIX 'string'}	Adds a specified suffix to the output file name before the extension. For example, use {$LIBSUFFIX '-2.1.3'} in something.pas to generate something-2.1.3.bpl.
{$LIBVERSION 'string'}	Adds a second extension to the output file name after the .bpl extension. For example, use {$LIBVERSION '2.1.3'} in something.pas to generate something.bpl.2.1.3.

Packages are special DLLs used by Delphi applications, the IDE, or both. There are two kinds of packages: runtime packages and design-time packages. Runtime packages provide functionality to a program while that program is running. Design-time packages extend the functionality of the IDE.

For more information on packages, see Working with packages and components. (see page 2211)

See Also

Working with Packages and Components: Overview (see page 2211)

3.2.4.1.1.3 Linking DLLs

You can set the linker options for your DLL on the Linker page of the **Project Options** dialog box. The default check box on this page also creates an import library for your DLL. If compiling from the command line, invoke the linker, `ilink32.exe`, with the `-Tpd` switch. For example:

```
ilink32 /c /aa /Tpd c0d32.obj mydll.obj, mydll.dll, mydll.map, import32.lib cw32mt.lib
```

If you need an import library, use the -Gi switch to generate an import library.

You can optionally create an import library with the command line utility implib.exe. For more information on implib.exe, type `implib –h` at the command line.

3.2.4.1.1.4 When to Use Packages and DLLs

For most applications, packages provide greater flexibility and are easier to create than DLLs. However, there are several situations where DLLs would be better suited to your projects than packages:

- Your code module will be called from non-Delphi applications.
- You are extending the functionality of a Web server.
- You are creating a code module to be used by third-party developers.
- Your project is an OLE container.

You cannot pass Delphi runtime type information (RTTI) across DLLs or from a DLL to an executable. If you pass an object from one DLL to another DLL or an executable, you will not be able to use the **is** or **as** operators with the passed object. This is because the **is** and **as** operators need to compare RTTI. If you need to pass objects from a library, use packages instead, as these can share RTTI. Similarly, you should use packages instead of DLLs in Web Services because they are rely on Delphi RTTI.

3.2.4.1.1.5 Using DLLs in RAD Studio (C++)

A Windows DLL can be used in a RAD Studio application just as it would be in any C++ application.

To statically load a DLL when your C++ application is loaded, link the import library file for that DLL into your C++ application at link time. To add an import library to a C++ application, choose Project->Add to Project and select the `.lib` file you want to add to the libraries to be linked.

The exported functions of that DLL then become available for use by your application. Prototype the DLL functions your application uses with the __declspec (dllimport) modifier:

```
__declspec(dllimport) return_type imported_function_name(parameters);
```

To dynamically load a DLL during the run of a C++ application, include the import library, just as you would for static loading, and set the Delay load a DLL option for `ilink32`. You can also use the Windows API function `LoadLibrary()` to load the DLL, then use the API function `GetProcAddress()` to obtain pointers to the individual functions you want to use.

3.2.4.1.2 Creating Applications

The most common types of applications you can design and build are:

- GUI applications (see page 1902)

- Console applications (see page 1900)
- Service applications (see page 1903)
- Packages and DLLs (see page 1882)

GUI applications generally have an easy-to-use interface. Console applications run from a console window. Service applications are run as Windows services. These types of applications compile as executables with start-up code.

You can create other types of projects such as packages and DLLs that result in creating packages or dynamically linkable libraries. These applications produce executable code without start-up code. Refer to Creating packages and DLLs (see page 1882).

Topics

Name	Description
Creating Web Services Applications (see page 1885)	Web Services are self-contained modular applications that can be published and invoked over a network (such as the World Wide Web). Web Services provide well-defined interfaces that describe the services provided. You use Web Services to produce or consume programmable services over the Internet using emerging standards such as XML, XML Schema, SOAP (Simple Object Access Protocol), and WSDL (Web Service Definition Language). Web Services use SOAP, a standard lightweight protocol for exchanging information in a distributed environment. It uses HTTP as a communications protocol and XML to encode remote procedure calls. You can build servers to implement Web Services... more (see page 1885)
Creating WebSnap Applications (see page 1885)	WebSnap provides a set of components and wizards for building advanced Web servers that interact with Web browsers. WebSnap components generate HTML or other MIME content for Web pages. WebSnap is for server-side development. To create a new WebSnap application, select File ▶ New ▶ Other and select the WebSnap tab in the New Items dialog box. Choose WebSnap Application. Then select the Web server application type (ISAPI/NSAPI, CGI, Apache). See the table in the topic Using Web Broker (see page 1885) for details. If you want to do client-side scripting instead of server-side scripting, you can use the InternetExpress technology. For more information on... more (see page 1885)
Creating Web Broker Applications (see page 1885)	You can use Web Broker to create Web server applications such as CGI applications or dynamic-link libraries (DLLs). These Web server applications can contain any nonvisual component. Components on the Internet category of the **Tool palette** enable you to create event handlers, programmatically construct HTML or XML documents, and transfer them to the client. To create a new Web server application using the Web Broker architecture, choose File ▶ New ▶ Other. In the New Items dialog box, select the Delphi Projects tab. Then select the New tab and double-click the Web Server Application. Then select the Web server application type:... more (see page 1885)
Creating Web Server Applications (see page 1886)	Web server applications are applications that run on servers that deliver Web content such as HTML Web pages or XML documents over the Internet. Examples of Web server applications include those which control access to a Web site, generate purchase orders, or respond to information requests. You can create several different types of Web server applications using the following technologies: • Web Broker (see page 1885) • WebSnap (see page 1885) • IntraWeb (see page 2259) • Web Services (see page 1885)

3.2.4.1.3.1 Creating Web Services Applications

Web Services are self-contained modular applications that can be published and invoked over a network (such as the World Wide Web). Web Services provide well-defined interfaces that describe the services provided. You use Web Services to produce or consume programmable services over the Internet using emerging standards such as XML, XML Schema, SOAP (Simple Object Access Protocol), and WSDL (Web Service Definition Language).

Web Services use SOAP, a standard lightweight protocol for exchanging information in a distributed environment. It uses HTTP as a communications protocol and XML to encode remote procedure calls.

You can build servers to implement Web Services and clients that call on those services. You can write clients for arbitrary servers to implement Web Services that respond to SOAP messages, and servers to publish Web Services for use by arbitrary clients.

Refer to Using Web Services (see page 2291) for more information on Web Services.

See Also

Creating Web Broker Applications (see page 1885)

Creating WebSnap Applications (see page 1885)

3.2.4.1.3.2 Creating WebSnap Applications

WebSnap provides a set of components and wizards for building advanced Web servers that interact with Web browsers. WebSnap components generate HTML or other MIME content for Web pages. WebSnap is for server-side development.

To create a new WebSnap application, select **File** ▶ **New** ▶ **Other** and select the WebSnap tab in the New Items dialog box. Choose WebSnap Application. Then select the Web server application type (ISAPI/NSAPI, CGI, Apache). See the table in the topic Using Web Broker (see page 1885) for details.

If you want to do client-side scripting instead of server-side scripting, you can use the InternetExpress technology. For more information on InternetExpress, see Building Web applications using InternetExpress (see page 1522).

For more information on WebSnap, see Creating Internet Server Applications. (see page 2251)

See Also

Creating Web Broker Applications (see page 1885)

Creating Web Services Applications (see page 1885)

3.2.4.1.3.3 Creating Web Broker Applications

You can use Web Broker to create Web server applications such as CGI applications or dynamic-link libraries (DLLs). These Web server applications can contain any nonvisual component. Components on the Internet category of the **Tool palette** enable you to create event handlers, programmatically construct HTML or XML documents, and transfer them to the client.

To create a new Web server application using the Web Broker architecture, choose **File** ▶ **New** ▶ **Other**. In the New Items dialog box, select the Delphi Projects tab. Then select the New tab and double-click the Web Server Application. Then select the Web server application type:

Web server applications

Web server application type	Description
ISAPI and NSAPI Dynamic Link Library	ISAPI and NSAPI Web server applications are DLLs that are loaded by the Web server. Client request information is passed to the DLL as a structure and evaluated by TISAPIApplication. Each request message is handled in a separate execution thread. Selecting this type of application adds the library header of the project files and required entries to the uses list and exports clause of the project file.
CGI Stand-alone executable	CGI Web server applications are console applications that receive requests from clients on standard input, process those requests, and sends back the results to the server on standard output to be sent to the client. Selecting this type of application adds the required entries to the uses clause of the project file and adds the appropriate $APPTYPE directive to the source.
Apache Shared Module (DLL)	Selecting this type of application sets up your project as a DLL. Apache Web server applications are DLLs loaded by the Web server. Information is passed to the DLL, processed, and returned to the client by the Web server.
Web App Debugger stand-alone executable	Selecting this type of application sets up an environment for developing and testing Web server applications. Web App Debugger applications are executable files loaded by the Web server. This type of application is not intended for deployment.

CGI applications use more system resources on the server, so complex applications are better created as ISAPI, NSAPI, or Apache DLL applications. When writing cross-platform applications, you should select CGI stand-alone or Apache Shared Module (DLL) for Web server development. These are also the same options you see when creating WebSnap and Web Service applications.

For more information on building Web server applications, see Creating Internet Server Applications. (see page 2251)

3.2.4.1.4 Enabling Help in applications

Topics

Name	Description
Asking the Help Manager for Information (see page 1890)	Help viewers communicate with the Help Manager through the *IHelpManager* interface, an instance of which is returned to them when they register with the Help Manager. *IHelpManager* allows the Help viewer to communicate four things: • A request for the window handle of the currently active control. • A request for the name of the Help file which the Help Manager believes should contain help for the currently active control. • A request for the path to that Help file. • A notification that the Help viewer is shutting itself down in response to something other than a request from the Help Manager that... more (see page 1890)
Calling a Help System Directly (see page 1890)	For additional Help system functionality not provided by VCL applications, *TApplication* provides a read-only property that allows direct access to the Help system. This property is an instance of an implementation of the interface *IHelpSystem*. *IHelpSystem* and *IHelpManager* are implemented by the same object, but one interface is used to allow the application to talk to the Help Manager, and one is used to allow the Help viewers to talk to the Help Manager.
Communicating with the Help Manager (see page 1890)	The ICustomHelpViewer provides four functions that can be used to communicate system information with the Help Manager: • *GetViewerName* • *NotifyID* • *ShutDown* • SoftShutDown The Help Manager calls through these functions in the following circumstances: • *ICustomHelpViewer.GetViewerName* : *String* is called when the Help Manager wants to know the name of the viewer (for example, if the application is asked to display a list of all registered viewers). This information is returned via a string, and is required to be logically static (that is, it cannot change during the operation of the application). Multibyte character sets are not supported. • *ICustomHelpViewer.NotifyID(const ViewerID: Integer)* is called... more (see page 1890)
Customizing the IDE Help System (see page 1891)	The IDE supports multiple Help viewers in exactly the same way that a VCL application does: it delegates Help requests to the Help Manager, which forwards them to registered Help viewers. The IDE makes use of the same WinHelpViewer that the VCL uses. The IDE comes with two Help viewers installed: the HyperHelp viewer, which allows Help requests to be forwarded to HyperHelp, an external WinHelp emulator under which the Kylix Help files are viewed, and the Man page viewer, which allows you to access the Man system installed on most Unix machines. Because it is necessary for Kylix... more (see page 1891)

Displaying Keyword-based Help (see page 1892)	Help requests typically come through to the Help viewer as either *keyword-based* Help, in which case the viewer is asked to provide help based upon a particular string, or as *context-based* Help, in which case the viewer is asked to provide help based upon a particular numeric identifier. **Note:** Numeric Help contexts are the default form of Help requests in applications running under Windows, which use the WinHelp system. *ICustomHelpViewer* implementations are required to provide support for keyword-based Help requests, while *IExtendedHelpViewer* implementations are required to support context-based Help requests. *ICustomHelpViewer* provides three methods for handling keyword-based Help: • *UnderstandsKeyword* • *GetHelpStrings... more (see page 1892)*
Displaying Tables of Contents (see page 1893)	*ICustomHelpViewer* provides two methods relating to displaying tables of contents: • *CanShowTableOfContents* • *ShowTableOfContents* The theory behind their operation is similar to the operation of the keyword Help request functions: the Help Manager first queries all Help viewers by calling *ICustomHelpViewer.CanShowTableOfContents : Boolean* and then invokes a particular Help viewer by calling *ICustomHelpViewer.ShowTableOfContents*. It is reasonable for a particular viewer to refuse to allow requests to support a table of contents. The Man page viewer does this, for example, because the concept of a table of contents does not map well to the way Man pages work; the HyperHelp viewer supports... more (see page 1893)
Enabling Help in Applications (see page 1893)	VCL applications support displaying Help using an object-based mechanism that allows Help requests to be passed on to one of multiple external Help viewers. To support this, an application must include a class that implements the *ICustomHelpViewer* interface (and, optionally, one of several interfaces descended from it), and registers itself with the global Help Manager. VCL applications provide an instance of *TWinHelpViewer*, which implements all of these interfaces and provides a link between applications and WinHelp. The Help Manager maintains a list of registered viewers and passes requests to them in a two-phase process: it first asks each viewer... more (see page 1893)
Help System Interfaces (see page 1894)	The Help system allows communication between your application and Help viewers through a series of interfaces. These interfaces are all defined in the HelpIntfs.pas, which also contains the implementation of the Help Manager. ICustomHelpViewer provides support for displaying Help based upon a provided keyword and for displaying a table of contents listing all Help available in a particular viewer. IExtendedHelpViewer provides support for displaying Help based upon a numeric Help context and for displaying topics; in most Help systems, topics function as high-level keywords (for example, "IntToStr" might be a keyword in the Help system, but "String manipulation routines" could... more (see page 1894)
How TApplication Processes VCL Help (see page 1895)	*TApplication* in the VCL provides four methods that are accessible from application code: ***Help methods in TApplication***
How VCL Controls Process Help (see page 1895)	All VCL controls that derive from *TControl* expose several properties that are used by the Help system: *HelpType*, *HelpContext*, and *HelpKeyword*. The *HelpType* property contains an instance of an enumerated type that determines if the control's designer expects help to be provided via keyword-based Help or context-based Help. If the *HelpType* is set to *htKeyword*, then the Help system expects the control to use keyword-based Help, and the Help system only looks at the contents of the *HelpKeyword* property. Conversely, if the *HelpType* is set to *htContext*, the Help system expects the control to use... more (see page 1895)

Implementing ICustomHelpViewer (see page 1895)	The ICustomHelpViewer interface contains three types of methods: methods used to communicate system-level information (for example, information not related to a particular Help request) with the Help Manager; methods related to showing Help based upon a keyword provided by the Help Manager; and methods for displaying a table of contents. For information on ICustomHelpViewer methods, see • Communicating with the Help Manager (see page 1890) • Displaying keyword-based Help (see page 1892) • Asking the Help Manager for information (see page 1890)
Implementing IExtendedHelpViewer (see page 1896)	*ICustomHelpViewer* only provides direct support for keyword-based Help. Some Help systems (especially WinHelp) work by associating numbers (known as *context IDs*) with keywords in a fashion which is internal to the Help system and therefore not visible to the application. Such systems require that the application support context-based Help in which the application invokes the Help system with that context, rather than with a string, and the Help system translates the number itself. Applications can talk to systems requiring context-based Help by extending the object that implements *ICustomHelpViewer* to also implement *IExtendedHelpViewer*. *IExtendedHelpViewer* also provides support for talking... more (see page 1896)
Implementing IHelpSelector (see page 1897)	*IHelpSelector* is a companion to *ICustomHelpViewer*. When more than one registered viewer claims to provide support for a given keyword, context, or topic, or provides a table of contents, the Help Manager must choose between them. In the case of contexts or topics, the Help Manager *always* selects the first Help viewer that claims to provide support. In the case of keywords or the table of context, the Help Manager will, by default, select the first Help viewer. This behavior can be overridden by an application. To override the decision of the Help Manager in such cases, an application... more (see page 1897)
Registering Help System Objects (see page 1897)	For the Help Manager to communicate with them, objects that implement *ICustomHelpViewer, IExtendedHelpViewer, ISpecialWinHelpViewer,* and *IHelpSelector* must register with the Help Manager. To register Help system objects with the Help Manager, you need to: • Register the Help viewer. • Register the Help Selector.
Using Help in a VCL Application (see page 1898)	The following sections explain how to use Help within a VCL application. • How TApplication Processes VCL Help (see page 1895) • How VCL controls process Help (see page 1895) • Calling a Help system directly (see page 1890) • Using IHelpSystem (see page 1898)
Using IHelpSystem (see page 1898)	*IHelpSystem* allows an application to do three things: • Provides path information to the Help Manager. • Provides a new Help selector. • Asks the Help Manager to display Help. Providing path information is important because the Help Manager is platform-independent and Help system-independent and so is not able to ascertain the location of Help files. If an application expects Help to be provided by an external Help system that is not able to ascertain file locations itself, it must provide this information through the *IHelpSystem's ProvideHelpPath* method, which allows the information to become available through the *IHelpManager's GetHelpPath* method. (This information propagates... more (see page 1898)

3.2.4.1.4.1 Asking the Help Manager for Information

Help viewers communicate with the Help Manager through the *IHelpManager* interface, an instance of which is returned to them when they register with the Help Manager. *IHelpManager* allows the Help viewer to communicate four things:

- A request for the window handle of the currently active control.
- A request for the name of the Help file which the Help Manager believes should contain help for the currently active control.
- A request for the path to that Help file.
- A notification that the Help viewer is shutting itself down in response to something other than a request from the Help Manager that it do so.

IHelpManager.GetHandle : *LongInt* is called by the Help viewer if it needs to know the handle of the currently active control; the result is a window handle.

IHelpManager.GetHelpFile: *String* is called by the Help viewer if it needs to know the name of the Help file which the currently active control believes contains its Help.

IHelpManager.Release is called to notify the Help Manager when a Help viewer is disconnecting. It should never be called in response to a request through *ICustomHelpViewer.ShutDown*; it is only used to notify the Help Manager of unexpected disconnects.

Implementing IHelpSelector (see page 1897)

Registering Help System Objects (see page 1897)

3.2.4.1.4.2 Calling a Help System Directly

For additional Help system functionality not provided by VCL applications, *TApplication* provides a read-only property that allows direct access to the Help system. This property is an instance of an implementation of the interface *IHelpSystem*. *IHelpSystem* and *IHelpManager* are implemented by the same object, but one interface is used to allow the application to talk to the Help Manager, and one is used to allow the Help viewers to talk to the Help Manager.

Enabling Help in Applications (see page 1893)

How TApplication Processes VCL Help (see page 1895)

3.2.4.1.4.3 Communicating with the Help Manager

The ICustomHelpViewer provides four functions that can be used to communicate system information with the Help Manager:

- *GetViewerName*
- *NotifyID*
- *ShutDown*
- SoftShutDown

The Help Manager calls through these functions in the following circumstances:

- *ICustomHelpViewer.GetViewerName* : *String* is called when the Help Manager wants to know the name of the viewer (for example, if the application is asked to display a list of all registered viewers). This information is returned via a string, and is required to be logically static (that is, it cannot change during the operation of the application). Multibyte character sets are not supported.
- *ICustomHelpViewer.NotifyID(const ViewerID: Integer)* is called **immediately** following registration to provide the viewer with a unique cookie that identifies it. This information must be stored off for later use; if the viewer shuts down on its own (as opposed to in response to a notification from the Help Manager), it must provide the Help Manager with the identifying cookie so that the Help Manager can release all references to the viewer. (Failing to provide the cookie, or providing the wrong one, causes the Help Manager to potentially release references to the wrong viewer.)
- *ICustomHelpViewer.ShutDown* is called by the Help Manager to notify the Help viewer that the Manager is shutting down and that any resources the Help viewer has allocated should be freed. It is recommended that all resource freeing be delegated to this method.
- *ICustomHelpViewer.SoftShutDown* is called by the Help Manager to ask the Help viewer to close any externally visible manifestations of the Help system (for example, windows displaying Help information) without unloading the viewer.

Registering Help System Objects (see page 1897)

3.2.4.1.4.4 Customizing the IDE Help System

The IDE supports multiple Help viewers in exactly the same way that a VCL application does: it delegates Help requests to the Help Manager, which forwards them to registered Help viewers. The IDE makes use of the same WinHelpViewer that the VCL uses.

The IDE comes with two Help viewers installed: the HyperHelp viewer, which allows Help requests to be forwarded to HyperHelp, an external WinHelp emulator under which the Kylix Help files are viewed, and the Man page viewer, which allows you to access the Man system installed on most Unix machines. Because it is necessary for Kylix Help to work, the HyperHelp viewer may not be removed; the Man page viewer ships in a separate package whose source is available in the examples directory.

To install a new Help viewer in the IDE, you do exactly what you would do in a VCL application, with one difference. You write an object that implements *ICustomHelpViewer* (and, if desired, *IExtendedHelpViewer*) to forward Help requests to the external viewer of your choice, and you register the *ICustomHelpViewer* with the IDE.

To register a custom Help viewer with the IDE:

1. Make sure that the unit implementing the Help viewer contains HelpIntfs.pas.
2. Build the unit into a design-time package registered with the IDE, and build the package with runtime packages turned on. (This is necessary to ensure that the Help Manager instance used by the unit is the same as the Help Manager instance used by the IDE.)
3. Make sure that the Help viewer exists as a global instance within the unit.
4. In the initialization section of the unit, make sure that the instance is passed to the *RegisterHelpViewer* function.

See Also

Enabling Help in Applications (see page 1893)

How TApplication Processes VCL Help (see page 1895)

3.2.4.1.4.5 Displaying Keyword-based Help

Help requests typically come through to the Help viewer as either *keyword-based* Help, in which case the viewer is asked to provide help based upon a particular string, or as *context-based* Help, in which case the viewer is asked to provide help based upon a particular numeric identifier.

Note: Numeric Help contexts are the default form of Help requests in applications running under Windows, which use the WinHelp system.

ICustomHelpViewer implementations are required to provide support for keyword-based Help requests, while *IExtendedHelpViewer* implementations are required to support context-based Help requests.

ICustomHelpViewer provides three methods for handling keyword-based Help:

- *UnderstandsKeyword*
- *GetHelpStrings*
- *ShowHelp*

```
ICustomHelpViewer.UnderstandsKeyword(const HelpString: String): Integer
int__fastcall ICustomHelpViewer::UnderstandsKeyword(const AnsiString HelpString)
```

is the first of the three methods called by the Help Manager, which will call each registered Help viewer with the same string to ask if the viewer provides help for that string; the viewer is expected to respond with an integer indicating how many different Help pages it can display in response to that Help request. The viewer can use any method it wants to determine this—inside the IDE, the HyperHelp viewer maintains its own index and searches it. If the viewer does not support help on this keyword, it should return zero. Negative numbers are currently interpreted as meaning zero, but this behavior is not guaranteed in future releases.

```
ICustomHelpViewer.GetHelpStrings(const HelpString: String): TStringList
Classes::TStringList*__fastcall ICustomHelpViewer::GetHelpStrings(const AnsiString HelpString)
```

is called by the Help Manager if more than one viewer can provide Help on a topic. The viewer is expected to return a *TStringList*, which is freed by the Help Manager. The strings in the returned list should map to the pages available for that keyword, but the characteristics of that mapping can be determined by the viewer. In the case of the WinHelp viewer on Windows and the HyperHelp viewer on Linux, the string list always contains exactly one entry. HyperHelp provides its own indexing, and duplicating that elsewhere would be pointless duplication. In the case of the Man page viewer (Linux), the string list consists of multiple strings, one for each section of the manual which contains a page for that keyword.

```
ICustomHelpViewer.ShowHelp(const HelpString: String)
void__fastcall ICustomHelpViewer::ShowHelp(const AnsiString HelpString)
```

is called by the Help Manager if it needs the Help viewer to display help for a particular keyword. This is the last method call in the operation; it is guaranteed to never be called unless the *UnderstandsKeyword* method is invoked first.

Displaying Tables of Contents (see page 1893)

Implementing IExtendedHelpViewer (see page 1896)

Implementing IHelpSelector (see page 1897)

Registering Help System Objects (see page 1897)

3.2.4.1.4.6 Displaying Tables of Contents

ICustomHelpViewer provides two methods relating to displaying tables of contents:

- *CanShowTableOfContents*
- *ShowTableOfContents*

The theory behind their operation is similar to the operation of the keyword Help request functions: the Help Manager first queries all Help viewers by calling *ICustomHelpViewer.CanShowTableOfContents : Boolean* and then invokes a particular Help viewer by calling *ICustomHelpViewer.ShowTableOfContents*.

It is reasonable for a particular viewer to refuse to allow requests to support a table of contents. The Man page viewer does this, for example, because the concept of a table of contents does not map well to the way Man pages work; the HyperHelp viewer supports a table of contents, on the other hand, by passing the request to display a table of contents directly to WinHelp on Windows and HyperHelp on Linux. It is not reasonable, however, for an implementation of *ICustomHelpViewer* to respond to queries through *CanShowTableOfContents* with the answer *True*, and then ignore requests through *ShowTableOfContents*.

3.2.4.1.4.7 Enabling Help in Applications

VCL applications support displaying Help using an object-based mechanism that allows Help requests to be passed on to one of multiple external Help viewers. To support this, an application must include a class that implements the *ICustomHelpViewer* interface (and, optionally, one of several interfaces descended from it), and registers itself with the global Help Manager.

VCL applications provide an instance of *TWinHelpViewer*, which implements all of these interfaces and provides a link between applications and WinHelp.

The Help Manager maintains a list of registered viewers and passes requests to them in a two-phase process: it first asks each viewer if it can provide support for a particular Help keyword or context, and then it passes the Help request on to the viewer which says it can provide such support.

If more than one viewer supports the keyword, as would be the case in an application that had registered viewers for both WinHelp and HyperHelp on Windows, the Help Manager can display a selection box through which the user of the application can determine which Help viewer to invoke. Otherwise, it displays the first responding Help system encountered.

Customizing the IDE Help System (see page 1891)

3.2.4.1.4.8 Help System Interfaces

The Help system allows communication between your application and Help viewers through a series of interfaces. These interfaces are all defined in the HelpIntfs.pas, which also contains the implementation of the Help Manager.

ICustomHelpViewer provides support for displaying Help based upon a provided keyword and for displaying a table of contents listing all Help available in a particular viewer.

IExtendedHelpViewer provides support for displaying Help based upon a numeric Help context and for displaying topics; in most Help systems, topics function as high-level keywords (for example, "IntToStr" might be a keyword in the Help system, but "String manipulation routines" could be the name of a topic).

ISpecialWinHelpViewer provides support for responding to specialized WinHelp messages that an application running under Windows may receive and which are not easily generalizable. In general, only applications operating in the Windows environment need to implement this interface, and even then it is only required for applications that make extensive use of non-standard WinHelp messages.

IHelpManager provides a mechanism for the Help viewer to communicate back to the application's Help Manager and request additional information. *IHelpManager* is obtained at the time the Help viewer registers itself.

IHelpSystem provides a mechanism through which *TApplication* passes Help requests on to the Help system. *TApplication* obtains an instance of an object which implements both *IHelpSystem* and *IHelpManager* at application load time and exports that instance as a property; this allows other code within the application to file Help requests directly when appropriate.

IHelpSelector provides a mechanism through which the Help system can invoke the user interface to ask which Help viewer should be used in cases where more than one viewer is capable of handling a Help request, and to display a Table of Contents. This display capability is not built into the Help Manager directly to allow the Help Manager code to be identical regardless of which widget set or class library is in use.

3.2.4.1.4.9 How TApplication Processes VCL Help

TApplication in the VCL provides four methods that are accessible from application code:

Help methods in TApplication

Method	Description
HelpCommand	Takes a Windows Help style HELP_COMMAND and passes it off to WinHelp. Help requests forwarded through this mechanism are passed only to implementations of IspecialWinHelpViewer.
HelpContext	Invokes the Help System with a request for context-based Help.
HelpKeyword	Invokes the HelpSystem with a request for keyword-based Help.
HelpJump	Requests the display of a particular topic.

All four functions take the data passed to them and forward it through a data member of *TApplication*, which represents the Help system. That data member is directly accessible through the property *HelpSystem*.

See Also

Enabling Help in Applications (see page 1893)

3.2.4.1.4.10 How VCL Controls Process Help

All VCL controls that derive from *TControl* expose several properties that are used by the Help system: *HelpType*, *HelpContext*, and *HelpKeyword*.

The *HelpType* property contains an instance of an enumerated type that determines if the control's designer expects help to be provided via keyword-based Help or context-based Help. If the *HelpType* is set to *htKeyword*, then the Help system expects the control to use keyword-based Help, and the Help system only looks at the contents of the *HelpKeyword* property. Conversely, if the *HelpType* is set to *htContext*, the Help system expects the control to use context-based Help and only looks at the contents of the *HelpContext* property.

In addition to the properties, controls expose a single method, *InvokeHelp*, that can be called to pass a request to the Help system. It takes no parameters and calls the methods in the global Application object, which correspond to the type of Help the control supports.

Help messages are automatically invoked when F1 is pressed because the *KeyDown* method of *TWinControl* calls *InvokeHelp*.

See Also

How TApplication Processes VCL Help (see page 1895)

3.2.4.1.4.11 Implementing ICustomHelpViewer

The ICustomHelpViewer interface contains three types of methods: methods used to communicate system-level information (for example, information not related to a particular Help request) with the Help Manager; methods related to showing Help based upon a keyword provided by the Help Manager; and methods for displaying a table of contents.

For information on ICustomHelpViewer methods, see

- Communicating with the Help Manager (see page 1890)
- Displaying keyword-based Help (see page 1892)
- Asking the Help Manager for information (see page 1890)

Implementing IExtendedHelpViewer (see page 1896)

Implementing IHelpSelector (see page 1897)

Registering Help System Objects (see page 1897)

3.2.4.1.4.12 Implementing IExtendedHelpViewer

ICustomHelpViewer only provides direct support for keyword-based Help. Some Help systems (especially WinHelp) work by associating numbers (known as *context IDs*) with keywords in a fashion which is internal to the Help system and therefore not visible to the application. Such systems require that the application support context-based Help in which the application invokes the Help system with that context, rather than with a string, and the Help system translates the number itself.

Applications can talk to systems requiring context-based Help by extending the object that implements *ICustomHelpViewer* to also implement *IExtendedHelpViewer*. *IExtendedHelpViewer* also provides support for talking to Help systems that allow you to jump directly to high-level topics instead of using keyword searches. The built-in WinHelp viewer does this for you automatically.

IExtendedHelpViewer exposes four functions. Two of them—*UnderstandsContext* and *DisplayHelpByContext*—are used to support context-based Help; the other two—*UnderstandsTopic* and *DisplayTopic*—are used to support topics.

When an application user presses F1, the Help Manager calls

```
IExtendedHelpViewer.UnderstandsContext(const ContextID: Integer;
const HelpFileName: String): Boolean
int__fastcall IExtendedHelpViewer::UnderstandsContext(const int ContextID, AnsiString
HelpFileName)
```

and the currently activated control supports context-based, rather than keyword-based Help. As with *ICustomHelpViewer.UnderstandsKeyword*, the Help Manager queries all registered Help viewers iteratively. Unlike the case with *ICustomHelpViewer.UnderstandsKeyword*, however, if more than one viewer supports a specified context, the first registered viewer with support for a given context is invoked.

The Help Manager calls

```
IExtendedHelpViewer.DisplayHelpByContext(const ContextID: Integer;
const HelpFileName: String)
void__fastcall IExtendedHelpViewer::DisplayHelpByContext(const int ContextID, AnsiString
HelpFileName)
```

after it has polled the registered Help viewers.

The topic support functions work the same way:

```
IExtendedHelpViewer.UnderstandsTopic(const Topic: String): Boolean
bool__fastcall IExtendedHelpViewer::UnderstandsTopic(const AnsiString Topic)
```

is used to poll the Help viewers asking if they support a topic;

```
IExtendedHelpViewer.DisplayTopic(const Topic: String)
void__fastcall IExtendedHelpViewer::DisplayTopic(const AnsiString Topic)
```

is used to invoke the first registered viewer which reports that it is able to provide help for that topic.

Displaying Tables of Contents (see page 1893)

Implementing IExtendedHelpViewer

Implementing IHelpSelector (see page 1897)

Registering Help System Objects (see page 1897)

3.2.4.1.4.13 Implementing IHelpSelector

IHelpSelector is a companion to *ICustomHelpViewer*. When more than one registered viewer claims to provide support for a given keyword, context, or topic, or provides a table of contents, the Help Manager must choose between them. In the case of contexts or topics, the Help Manager *always* selects the first Help viewer that claims to provide support. In the case of keywords or the table of context, the Help Manager will, by default, select the first Help viewer. This behavior can be overridden by an application.

To override the decision of the Help Manager in such cases, an application must register a class that provides an implementation of the *IHelpSelector* interface. *IHelpSelector* exports two functions: *SelectKeyword*, and *TableOfContents*. Both take as arguments a TStrings containing, one by one, either the possible keyword matches or the names of the viewers claiming to provide a table of contents. The implementor is required to return the index (in the *TStringList*) that represents the selected string; the *TStringList* is then freed by the Help Manager.

Note: The Help Manager may get confused if the strings are rearranged; it is recommended that implementors of *IHelpSelector* refrain from doing this. The Help system only supports *one* HelpSelector; when new selectors are registered, any previously existing selectors are disconnected.

Registering Help System Objects (see page 1897)

3.2.4.1.4.14 Registering Help System Objects

For the Help Manager to communicate with them, objects that implement *ICustomHelpViewer, IExtendedHelpViewer, ISpecialWinHelpViewer,* and *IHelpSelector* must register with the Help Manager.

To register Help system objects with the Help Manager, you need to:

- Register the Help viewer.
- Register the Help Selector.

Registering Help viewers

The unit that contains the object implementation must use HelpIntfs. An instance of the object must be declared in the **var** section of the implementing unit.

The initialization section of the implementing unit must assign the instance variable and pass it to the function *RegisterViewer*. *RegisterViewer* is a flat function exported by the HelpIntfs unit, which takes as an argument an *ICustomHelpViewer* and returns an *IHelpManager*. The *IHelpManager* should be stored for future use.

Registering Help selectors

The unit that contains the object implementation must use Forms in the VCL. An instance of the object must be declared in the **var** section of the implementing unit.

The initialization section of the implementing unit must register the Help selector through the *HelpSystem* property of the global Application object:

```
Application.HelpSystem.AssignHelpSelector(myHelpSelectorInstance)
Application->HelpSystem->AssignHelpSelector(myHelpSelectorInstance)
```

This procedure does not return a value.

3.2.4.1.4.15 Using Help in a VCL Application

The following sections explain how to use Help within a VCL application.

- How TApplication Processes VCL Help (see page 1895)
- How VCL controls process Help (see page 1895)
- Calling a Help system directly (see page 1890)
- Using IHelpSystem (see page 1898)

See Also

Enabling Help in Applications (see page 1893)

3.2.4.1.4.16 Using IHelpSystem

IHelpSystem allows an application to do three things:

- Provides path information to the Help Manager.
- Provides a new Help selector.
- Asks the Help Manager to display Help.

Providing path information is important because the Help Manager is platform-independent and Help system-independent and so is not able to ascertain the location of Help files. If an application expects Help to be provided by an external Help system that is not able to ascertain file locations itself, it must provide this information through the *IHelpSystem's ProvideHelpPath* method, which allows the information to become available through the *IHelpManager's GetHelpPath* method. (This information propagates outward only if the Help viewer asks for it.)

Assigning a Help selector allows the Help Manager to delegate decision-making in cases where multiple external Help systems can provide Help for the same keyword. For more information, see the topic Implementing IHelpSelector (see page 1897).

IHelpSystem exports four procedures and one function to request the Help Manager to display Help:

- *ShowHelp*
- *ShowContextHelp*
- *ShowTopicHelp*
- *ShowTableOfContents*
- *Hook*

Hook is intended entirely for WinHelp compatibility; it allows processing of WM_HELP messages that cannot be mapped directly onto requests for keyword-based, context-based, or topic-based Help. The other methods each take two arguments: the keyword, context ID, or topic for which help is being requested, and the Help file in which it is expected that help can be found.

In general, unless you are asking for topic-based help, it is equally effective and more clear to pass help requests to the Help Manager through the *InvokeHelp* method of your control.

3.2.4.1.5 GUI applications

Topics

Name	Description
Setting IDE, Project, and Compiler Options (see page 1900)	In addition to the implementation model of your applications, the design-time behavior of your project and the runtime behavior of your application can be manipulated by setting project options in the IDE. To specify various options for your project, choose **Project** ▶ **Options**.
Console Applications (see page 1900)	Console applications are 32-bit programs that run without a graphical interface, in a console window. These applications typically don't require much user input and perform a limited set of functions. Any application that contains:
MDI Applications (see page 1901)	
SDI Applications (see page 1901)	
User Interface Models (see page 1902)	Any form can be implemented as a single document interface (SDI) or multiple document interface (MDI) form. An SDI application (see page 1901) normally contains a single document view. In an MDI application, more than one document or child window can be opened within a single parent window. This is common in applications such as spreadsheets or word processors. For more information on developing the UI for an application, see Developing the application user interface (see page 1983).

GUI Applications (see page 1902)	A graphical user interface (GUI) application is one that is designed using graphical features such as windows, menus, dialog boxes, and features that make the application easy to use. When you compile a GUI application, an executable file with start-up code is created. The executable usually provides the basic functionality of your program, and simple programs often consist of only an executable file. You can extend the application by calling DLLs, packages, and other support files from the executable. The IDE offers two application UI models: • Single document interface (see page 1901) (SDI) • Multiple document interface (see page 1901) (MDI) In addition to the implementation model... more (see page 1902)

3.2.4.1.5.1 Setting IDE, Project, and Compiler Options

In addition to the implementation model of your applications, the design-time behavior of your project and the runtime behavior of your application can be manipulated by setting project options in the IDE. To specify various options for your project, choose **Project ▸ Options**.

Setting default project options

To change the default options that apply to all future projects, set the options in the Project Options dialog box and check the **Default** box at the bottom left of each page. All new projects will use the current options selected by default.

See Also

Project Options

3.2.4.1.5.2 Console Applications

Console applications are 32-bit programs that run without a graphical interface, in a console window. These applications typically don't require much user input and perform a limited set of functions. Any application that contains:

```
{$APPTYPE CONSOLE}
```

in the code opens a console window of its own.

To create a new console application, choose **File ▸ New ▸ Other**. Select Delphi Projects and double-click Console Application from the New Items dialog box.

The IDE then creates a project file for this type of source file and displays the Code editor.

Console applications should make sure that no exceptions escape from the program scope. Otherwise, when the program terminates, the Windows operating system displays a modal dialog with exception information. For example, your application should include exception handling such as shown in the following code:

```
program ConsoleExceptionHandling;
{$APPTYPE CONSOLE}
uses
SysUtils;
procedure ExecuteProgram;
begin
  //Program does something
  raise Exception.Create('Unforeseen exception');
end;
begin
  try
    ExecuteProgram;
  except
//Handle error condition
    WriteIn('Program terminated due to an exception');
    //Set ExitCode <> 0 to flag error condition (by convention)
```

```
    ExitCode := 1;
  end;
end.
```

Users can terminate console applications in one of the following ways:

- Click the Close (X) button.
- Press `Ctrl+C`.
- Press `Ctrl+Break`.
- Log off.

Depending on which way the user chooses, the application is terminated forcefully, the process is not shut down cleanly, and the finalization section isn't run. Use the Windows API *SetConsoleCtrlHandler* function for options for handling these user termination requests.

TApplication

3.2.4.1.5.3 MDI Applications

To create a new MDI application using a wizard:

1. Choose **File** ▸ **New** ▸ **Other** to bring up the New Items dialog.
2. Click on the Projects page and double-click MDI Application.
3. Click OK.

MDI applications require more planning and are somewhat more complex to design than SDI applications. MDI applications spawn child windows that reside within the client window; the main form contains child forms. Set the *FormStyle* property of the *TForm* object to specify whether a form is a child (*fsMDIChild*) or main form (*fsMDIForm*). It is a good idea to define a base class for your child forms and derive each child form from this class, to avoid having to reset the child form's properties.

MDI applications often include a Window pop-up on the main menu that has items such as Cascade and Tile for viewing multiple windows in various styles. When a child window is minimized, its icon is located in the MDI parent form.

To create a new MDI application without using a wizard:

1. Create the main window form or MDI parent window. Set its *FormStyle* property to *fsMDIForm*.
2. Create a menu for the main window that includes **File** ▸ **Open**, **File** ▸ **Save**, and Window which has Cascade, Tile, and Arrange All items.
3. Create the MDI child forms and set their *FormStyle* properties to *fsMDIChild*.

TApplication

3.2.4.1.5.4 SDI Applications

To create a new SDI application:

1. Choose **File** ▸ **New** ▸ **Other** to bring up the New Items dialog.
2. Click on the Projects page and double-click SDI Application.
3. Click OK.

By default, the *FormStyle* property of your *Form* object is set to fsNormal, so that the IDE assumes that all new applications are SDI applications.

TApplication

3.2.4.1.6 Service applications

Topics

Name	Description
Debugging Service Applications (see page 1903)	You can debug service applications by attaching to the service application process when it is already running (that is, by starting the service first, and then attaching to the debugger). To attach to the service application process, choose **Run** ▶ **Attach To Process**, and select the service application in the resulting dialog. In some cases, this approach may fail, due to insufficient rights. If that happens, you can use the Service Control Manager to enable your service to work with the debugger:

Service Applications (see page 1903)	Service applications take requests from client applications, process those requests, and return information to the client applications. They typically run in the background, without much user input. A Web, FTP, or e-mail server is an example of a service application.
Service Name Properties (see page 1906)	The VCL provides classes for creating service applications on the Windows platform (not available for cross-platform applications). These include *TService* and *TDependency*. When using these classes, the various name properties can be confusing. This topic describes the differences. Services have user names (called Service start names) that are associated with passwords, display names for display in manager and editor windows, and actual names (the name of the service). Dependencies can be services or they can be load ordering groups. They also have names and display names. And because service objects are derived from *TComponent*, they inherit the *Name... more (see page 1906)*
Service Threads (see page 1907)	Each service has its own thread (TServiceThread), so if your service application implements more than one service you must ensure that the implementation of your services is thread-safe. *TServiceThread* is designed so that you can implement the service in the *TServiceOnExecute* event handler. The service thread has its own Execute method which contains a loop that calls the service's *OnStart* and *OnExecute* handlers before processing new requests. Because service requests can take a long time to process and the service application can receive simultaneous requests from more than one client, it is more efficient to spawn a new thread... more (see page 1907)

3.2.4.1.6.1 Debugging Service Applications

You can debug service applications by attaching to the service application process when it is already running (that is, by starting the service first, and then attaching to the debugger). To attach to the service application process, choose **Run ▸ Attach To Process**, and select the service application in the resulting dialog.

In some cases, this approach may fail, due to insufficient rights. If that happens, you can use the Service Control Manager to enable your service to work with the debugger:

To debug:

1. First create a key called **Image File Execution Options** in the following registry location:

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion
```

2. Create a subkey with the same name as your service (for example, MYSERV.EXE). To this subkey, add a value of type REG_SZ, named Debugger. Use the full path to bds.exe as the string value.
3. In the Services control panel applet, select your service, click Startup and check Allow Service to Interact with Desktop.

On Windows NT systems, you can use another approach for debugging service applications. However, this approach can be tricky, because it requires short time intervals:

For Windows NT:

1. First, launch the application in the debugger. Wait a few seconds until it has finished loading.
2. Quickly start the service from the Control Panel or from the command line:

```
start MyServ
```

You must launch the service quickly (within 15-30 seconds of application startup) because the application will terminate if no service is launched.

3.2.4.1.6.2 Service Applications

Service applications take requests from client applications, process those requests, and return information to the client applications. They typically run in the background, without much user input. A Web, FTP, or e-mail server is an example of a service application.

To create an application that implements a Win32 service:

1. Choose **File** ▸ **New** ▸ **Other**, and double-click Service Application in the New Items dialog box. This adds a global variable named *Application* to your project, which is of type *TServiceApplication*.
2. A Service window appears that corresponds to a service (*TService*). Implement the service by setting its properties and event handlers in the **Object Inspector**.
3. You can add additional services to your service application by choosing **File** ▸ **New** ▸ **Other**, and double-click Service in the New Items dialog box. Do not add services to an application that is not a service application. While a *TService* object can be added, the application will not generate the requisite events or make the appropriate Windows calls on behalf of the service.
4. Once your service application is built, you can install its services with the Service Control Manager (SCM). Other applications can then launch your services by sending requests to the SCM.

To install your application's services, run it using the /INSTALL option. The application installs its services and exits, giving a confirmation message if the services are successfully installed. You can suppress the confirmation message by running the service application using the /SILENT option.

To uninstall the services, run it from the command line using the /UNINSTALL option. (You can also use the /SILENT option to suppress the confirmation message when uninstalling).

Note: This service has a *TServerSocket* whose port is set to 80. This is the default port for Web browsers to make requests to Web servers and for Web servers to make responses to Web browsers. This particular example produces a text document in the C:\Temp directory called WebLog*xxx*.log (where *xxx* is the ThreadID). There should be only one server listening on any given port, so if you have a Web server, you should make sure that it is not listening (the service is stopped).

To see the results: open up a Web browser on the local machine and for the address, type 'localhost' (with no quotes). The browser will time out eventually, but you should now have a file called Weblog*xxx*.log in the C:\Temp directory.

To create the example:

1. Choose **File** ▸ **New** ▸ **Other** and select Service Application from the New Items dialog box. The Service1 window appears.
2. From the Internet category of the **Tool palette**, add a ServerSocket component to the service window (Service1).
3. Add a private data member of type TMemoryStream to the TService1 class. The interface section of your unit should now look like this:

```
interface
uses
  Windows, Messages, SysUtils, Classes, Graphics, Controls, SvcMgr, Dialogs,
  ScktComp;
type
    TService1 = class(TService)
    ServerSocket1: TServerSocket;
    procedure ServerSocket1ClientRead(Sender: TObject;
      Socket: TCustomWinSocket);
    procedure Service1Execute(Sender: TService);
  private
    { Private declarations }
    Stream: TMemoryStream; // Add this line here
  public
    function GetServiceController: PServiceController; override;
    { Public declarations }
  end;
var
  Service1: TService1;
//---------------------------------------------------------------------------
#ifndef Unit1H
#define Unit1H
//---------------------------------------------------------------------------
#include <SysUtils.hpp>
#include <Classes.hpp>
#include <SvcMgr.hpp>
#include <ScktComp.hpp>
//---------------------------------------------------------------------------
```

```
class TService1 : public TService
{
__published:
TServerSocket *ServerSocket1;
private:
TMemoryStream *Stream; // add this line here
public:
__fastcall TService1(TComponent* Owner);
PServiceController __fastcall GetServiceController(void);
friend void __stdcall ServiceController(unsigned CtrlCode);
};
//---------------------------------------------------------------------------
extern PACKAGE TService1 *Service1;
//---------------------------------------------------------------------------
#endif
```

4. Select ServerSocket1, the component you added in step 1. In the **Object Inspector**, double-click the OnClientRead event and add the following event handler:

```
procedure TService1.ServerSocket1ClientRead(Sender: TObject;
  Socket: TCustomWinSocket);
var
  Buffer: PChar;
begin
  Buffer := nil;
while Socket.ReceiveLength > 0 do begin
    Buffer := AllocMem(Socket.ReceiveLength);
    try
      Socket.ReceiveBuf(Buffer^, Socket.ReceiveLength);
      Stream.Write(Buffer^, StrLen(Buffer));
    finally
                  FreeMem(Buffer);
    end;
  Stream.Seek(0, soFromBeginning);
  Stream.SaveToFile('c:\Temp\Weblog' + IntToStr(ServiceThread.ThreadID) + '.log');
  end;
end;
void __fastcall TService1::ServerSocket1ClientRead(TObject *Sender,
TCustomWinSocket *Socket)
{
char *Buffer = NULL;
int len = Socket->ReceiveLength();
while (len > 0)
{
try
{
Buffer = (char *)malloc(len);
Socket->ReceiveBuf((void *)Buffer, len);
Stream->Write(Buffer, len);
}
__finally
{
free(Buffer);
}
Stream->Seek(0, soFromBeginning);
AnsiString LogFile = "C:\\Temp\\WebLog";
LogFile = LogFile + IntToStr(ServiceThread->ThreadID) + ".log";
Stream->SaveToFile(LogFile);
}
}
```

5. Finally, select Service1 by clicking in the window's client area (but not on the ServiceSocket). In the **Object Inspector**, double click the OnExecute event and add the following event handler:

```
procedure TService1.Service1Execute(Sender: TService);
begin
  Stream := TMemoryStream.Create;
```

```
    try
      ServerSocket1.Port := 80; // WWW port
      ServerSocket1.Active := True;
      while not Terminated do begin
        ServiceThread.ProcessRequests(True);
      end;
      ServerSocket1.Active := False;
    finally
      Stream.Free;
    end;
  end;
  void __fastcall TService1::Service1Execute(TService *Sender)
  {
  Stream = new TMemoryStream();
  try
  {
  ServerSocket1->Port = 80; // WWW port
  ServerSocket1->Active = true;
  while (!Terminated)
  ServiceThread->ProcessRequests(true);
  ServerSocket1->Active = false;
  }
  __finally
  {
  delete Stream;
  }
  }
```

When writing your service application, you should be aware of:

- Service threads (see page 1907)
- Service name properties (see page 1906)
- Debugging service applications (see page 1903)

Note: Service applications are not available for cross-platform applications.

3.2.4.1.6.3 Service Name Properties

The VCL provides classes for creating service applications on the Windows platform (not available for cross-platform applications). These include *TService* and *TDependency*. When using these classes, the various name properties can be confusing. This topic describes the differences.

Services have user names (called Service start names) that are associated with passwords, display names for display in manager and editor windows, and actual names (the name of the service). Dependencies can be services or they can be load ordering groups. They also have names and display names. And because service objects are derived from *TComponent*, they inherit the *Name* property. The following sections summarize the name properties.

TDependency properties

The *TDependency DisplayName* is both a display name and the actual name of the service. It is nearly always the same as the *TDependency Name* property.

TService name properties

The *TService Name* property is inherited from *TComponent*. It is the name of the component, and is also the name of the service. For dependencies that are services, this property is the same as the *TDependency Name* and *DisplayName* properties.

TService's DisplayName is the name displayed in the Service Manager window. This often differs from the actual service name

(*TService.Name, TDependency.DisplayName, TDependency.Name*). Note that the *DisplayName* for the Dependency and the *DisplayName* for the Service usually differ.

Service start names are distinct from both the service display names and the actual service names. A *ServiceStartName* is the user name input on the Start dialog selected from the Service Control Manager.

TDependency

3.2.4.1.6.4 Service Threads

Each service has its own thread (TServiceThread), so if your service application implements more than one service you must ensure that the implementation of your services is thread-safe. *TServiceThread* is designed so that you can implement the service in the *TServiceOnExecute* event handler. The service thread has its own Execute method which contains a loop that calls the service's *OnStart* and *OnExecute* handlers before processing new requests.

Because service requests can take a long time to process and the service application can receive simultaneous requests from more than one client, it is more efficient to spawn a new thread (derived from TThread, not *TServiceThread*) for each request and move the implementation of that service to the new thread's *Execute* method. This allows the service thread's *Execute* loop to process new requests continually without having to wait for the service's *OnExecute* handler to finish. The following example demonstrates.

Note: This service beeps every 500 milliseconds from within the standard thread. It handles pausing, continuing, and stopping of the thread when the service is told to pause, continue, or stop.

To create the example:

1. Choose **File** ▶ **New** ▶ **Other** and double-click Service Application in the New Items dialog. The Service1 window appears.
2. In the interface section of your unit, declare a new descendant of TThread named TSparkyThread. This is the thread that does the work for your service. The declaration should appear as follows:

```
TSparkyThread = class(TThread)
  public
    procedure Execute; override;
end;
```

```
class TSparkyThread : public TThread
{
private:
protected:
  void __fastcall Execute();
public:
__fastcall TSparkyThread(bool CreateSuspended);
};
```

3. In the implementation section of your unit, create a global variable for a TSparkyThread instance:

```
var
  SparkyThread: TSparkyThread;
```

```
TSparkyThread *SparkyThread;// Add this code as the constructor
__fastcall TSparkyThread::TSparkyThread(bool CreateSuspended)
: TThread(CreateSuspended)
{
}
```

4. In the implementation section for the TSparkyThread Execute method (the thread function), add the following code:

```
procedure TSparkyThread.Execute;
begin
  while not Terminated do
```

```
  begin
    Beep;
    Sleep(500);
  end;
end;
void __fastcall TSparkyThread::Execute()
{
  while (!Terminated)
  {
    Beep();
    Sleep(500);
  }
}
```

5. Select the Service window (Service1), and double-click the OnStart event in the **Object Inspector**. Add the following OnStart event handler:

```
procedure TService1.Service1Start(Sender: TService; var Started: Boolean);
begin
  SparkyThread := TSparkyThread.Create(False);
  Started := True;
end;
void __fastcall TService1::Service1Start(TService *Sender, bool &Started)
{
  SparkyThread = new TSparkyThread(false);
  Started = true;
}
```

6. Double-click the OnContinue event in the **Object Inspector**. Add the following OnContinue event handler:

```
procedure TService1.Service1Continue(Sender: TService; var Continued: Boolean);
begin
  SparkyThread.Resume;
  Continued := True;
end;
void __fastcall TService1::Service1Continue(TService *Sender, bool &Continued)
{
  SparkyThread->Resume();
  Continued = true;
}
```

7. Double-click the OnPause event in the **Object Inspector**. Add the following OnPause event handler:

```
procedure TService1.Service1Pause(Sender: TService; var Paused: Boolean);
begin
  SparkyThread.Suspend;
  Paused := True;
end;
void __fastcall TService1::Service1Pause(TService *Sender, bool &Paused)
{
  SparkyThread->Suspend();
  Paused = true;
}
```

8. Finally, double-click the OnStop event in the **Object Inspector** and add the following OnStop event handler:

```
procedure TService1.Service1Stop(Sender: TService; var Stopped: Boolean);
begin
  SparkyThread.Terminate;
  Stopped := True;
end;
void __fastcall TService1::Service1Stop(TService *Sender, bool &Stopped)
{
  SparkyThread->Terminate();
  Stopped = true;
}
```

When developing server applications, choosing to spawn a new thread depends on the nature of the service being provided, the anticipated number of connections, and the expected number of processors on the computer running the service.

3.2.4.1.7 Using data modules

Topics

Name	Description
Accessing a Data Module from a Form (see page 1910)	To associate visual controls on a form with a data module, you must first add the data module to the form's **uses** clause. You can do this in several ways: • In the Code editor, open the form's unit file and add the name of the data module to the **uses** clause in the **interface** section. • Click the form's unit file, choose **File ▶ Use Unit**, and enter the name of the module or pick it from the list box in the Use Unit dialog. • For database components, in the data module click a dataset or query component to open the... more (see page 1910)
Adding a Remote Data Module to an Application Server Project (see page 1910)	Some editions of Delphi allow you to add *remote data modules* to application server projects. A remote data module has an interface that clients in a multi-tiered application can access across networks.
Creating and Editing Standard Data Modules (see page 1911)	To create a standard data module for a project, choose **File ▶ New ▶ Other ▶ Delphi Projects ▶ Delphi Files ▶ Data Module**. The IDE opens a data module container on the desktop, displays the unit file for the new module in the Code editor, and adds the module to the current project. At design time, a data module looks like a standard form with a white background and no alignment grid. As with forms, you can place nonvisual components from the **Tool palette** onto a module, and edit their properties in the **Object Inspector**. You can resize a data module to... more (see page 1911)
Creating Business Rules in a Data Module (see page 1911)	Besides writing event handlers for the components in a data module, you can code methods directly in the unit file for a data module. These methods can be applied to the forms that use the data module as business rules. For example, you might write a procedure to perform month-, quarter-, or year-end bookkeeping. You might call the procedure from an event handler for a component in the data module. The prototypes for the procedures and functions you write for a data module should appear in the module's **type** declaration:
Using Data Modules (see page 1912)	A data module is like a special form that contains nonvisual components. All the components in a data module *could* be placed on ordinary forms alongside visual controls. But if you plan on reusing groups of database and system objects, or if you want to isolate the parts of your application that handle database connectivity and business rules, then data modules provide a convenient organizational tool. There are several types of data modules, including standard, remote, Web modules, applet modules, and services, depending on which edition of Delphi you have. Each type of data module serves a special purpose. • Standard... more (see page 1912)
Naming a Data Module and Its Unit File (see page 1912)	The title bar of a data module displays the module's name. The default name for a data module is "DataModule*N*" where *N* is a number representing the lowest unused unit number in a project. For example, if you start a new project, and add a module to it before doing any other application building, the name of the module defaults to "DataModule2." The corresponding unit file for *DataModule2* defaults to "Unit2." You should rename your data modules and their corresponding unit files at design time to make them more descriptive. You should especially rename data modules you add... more (see page 1912)

Placing and Naming Components (see page 1913)	You place nonvisual components in a data module just as you place visual components on a form. Click the desired component on the appropriate category of the **Tool palette**, then click in the data module to place the component. You cannot place visual controls, such as grids, on a data module. If you attempt it, you receive an error message. For ease of use, components are displayed with their names in a data module. When you first place a component, the module assigns it a generic name that identifies what kind of component it is, followed by a 1.... more (see page 1913)
Using Component Properties and Events in a Data Module (see page 1913)	Placing components in a data module centralizes their behavior for your entire application. For example, you can use the properties of dataset components, such as *TClientDataSet*, to control the data available to the data source components that use those datasets. Setting the *ReadOnly* property to *True* for a dataset prevents users from editing the data they see in a data-aware visual control on a form. You can also invoke the Fields editor for a dataset, by double-clicking on *ClientDataSet1*, to restrict the fields within a table or query that are available to a data source and therefore to... more (see page 1913)

3.2.4.1.7.1 Accessing a Data Module from a Form

To associate visual controls on a form with a data module, you must first add the data module to the form's **uses** clause. You can do this in several ways:

- In the Code editor, open the form's unit file and add the name of the data module to the **uses** clause in the **interface** section.
- Click the form's unit file, choose **File ▸ Use Unit**, and enter the name of the module or pick it from the list box in the Use Unit dialog.
- For database components, in the data module click a dataset or query component to open the Fields editor and drag any existing fields from the editor onto the form. The IDE prompts you to confirm that you want to add the module to the form's **uses** clause, then creates controls (such as edit boxes) for the fields.

For example, if you've added the *TClientDataSet* component to your data module, double-click it to open the Fields editor. Select a field and drag it to the form. An edit box component appears.

Because the data source is not yet defined, Delphi adds a new data source component, *DataSource1*, to the form and sets the edit box's *DataSource* property to *DataSource1*. The data source automatically sets its *DataSet* property to the dataset component, *ClientDataSet1*, in the data module.

You can define the data source *before* you drag a field to the form by adding a TDataSource component to the data module. Set the data source's *DataSet* property to *ClientDataSet1*. After you drag a field to the form, the edit box appears with its *TDataSource* property already set to *DataSource1*. This method keeps your data access model cleaner.

See Also

Using Data Modules and Remote Data Modules (see page 1912)

Creating and Editing Data Modules (see page 1911)

3.2.4.1.7.2 Adding a Remote Data Module to an Application Server Project

Some editions of Delphi allow you to add *remote data modules* to application server projects. A remote data module has an interface that clients in a multi-tiered application can access across networks.

To add a remote data module to a project:

1. Choose **File ▸ New ▸ Other**.
2. Select the ActiveX page in the New Items dialog box.
3. Double-click the Remote Data Module icon to open the Remote Data Module wizard.

Once you add a remote data module to a project, use it just like a standard data module.

For more information about multi-tiered database applications, see Creating multi-tiered applications (see page 1518).

See Also

Using Data Modules and Remote Data Modules (see page 1912)

3.2.4.1.7.3 Creating and Editing Standard Data Modules

To create a standard data module for a project, choose **File** ▶ **New** ▶ **Other** ▶ **Delphi Projects** ▶ **Delphi Files** ▶ **Data Module**. The IDE opens a data module container on the desktop, displays the unit file for the new module in the Code editor, and adds the module to the current project.

At design time, a data module looks like a standard form with a white background and no alignment grid. As with forms, you can place nonvisual components from the **Tool palette** onto a module, and edit their properties in the **Object Inspector**. You can resize a data module to accommodate the components you add to it.

You can also right-click a module to display a context menu for it. The following table summarizes the context menu options for a data module.

Context menu options for data modules

Menu item	Purpose
Edit	Displays a context menu with which you can cut, copy, paste, delete, and select the components in the data module.
Position	Aligns nonvisual components to the module's invisible grid (*Align To Grid*) *or* according to criteria you supply in the Alignment dialog box (*Align*).
Tab Order	Enables you to change the order that the focus jumps from component to component when you press the tab key.
Creation Order	Enables you to change the order that data access components are created at start-up.
Revert to Inherited	Discards changes made to a module inherited from another module in the Object Repository, and reverts to the originally inherited module.
Add to Repository	Stores a link to the data module in the Object Repository.
View as Text	Displays the text representation of the data module's properties.
Text DFM	Toggles between the formats (binary or text) in which this particular form file is saved.

See Also

Using Data Modules and Remote Data Modules (see page 1912)

3.2.4.1.7.4 Creating Business Rules in a Data Module

Besides writing event handlers for the components in a data module, you can code methods directly in the unit file for a data module. These methods can be applied to the forms that use the data module as business rules. For example, you might write a procedure to perform month-, quarter-, or year-end bookkeeping. You might call the procedure from an event handler for a component in the data module.

The prototypes for the procedures and functions you write for a data module should appear in the module's **type** declaration:

```
type
  TCustomerData = class(TDataModule)
    Customers: TClientDataSet;
    Orders: TClientDataSet;
    .
    .
    .
  private
    { Private declarations }
  public
    { Public declarations }
```

```
    procedure LineItemsCalcFields(DataSet: TDataSet); { A procedure you add }
  end;
var
  CustomerData: TCustomerData;
```

The procedures and functions you write should follow in the implementation section of the code for the module.

See Also

Designing Database Applications (see page 1566)

3.2.4.1.7.5 Using Data Modules

A data module is like a special form that contains nonvisual components. All the components in a data module *could* be placed on ordinary forms alongside visual controls. But if you plan on reusing groups of database and system objects, or if you want to isolate the parts of your application that handle database connectivity and business rules, then data modules provide a convenient organizational tool.

There are several types of data modules, including standard, remote, Web modules, applet modules, and services, depending on which edition of Delphi you have. Each type of data module serves a special purpose.

- Standard data modules are particularly useful for single- and two-tiered database applications, but can be used to organize the nonvisual components in any application. For more information, see Creating and Editing Data Modules (see page 1911).
- Remote data modules form the basis of an application server in a multi-tiered database application. They are not available in all editions. In addition to holding the nonvisual components in the application server, remote data modules expose the interface that clients use to communicate with the application server. For more information about using them, see Adding a remote data module to an application server project (see page 1910).
- Web modules form the basis of Web server applications. In addition to holding the components that create the content of HTTP response messages, they handle the dispatching of HTTP messages from client applications. See Creating Internet Server Applications (see page 2251) for more information about using Web modules.
- Applet modules form the basis of control panel applets. In addition to holding the nonvisual controls that implement the control panel applet, they define the properties that determine how the applet's icon appears in the control panel and include the events that are called when users execute the applet.
- Services encapsulate individual services in an NT service application. In addition to holding any nonvisual controls used to implement a service, services include the events that are called when the service is started or stopped. For more information about services, see Service Applications (see page 1903).

See Also

Designing Database Applications (see page 1566)

Creating and Editing Data Modules (see page 1911)

3.2.4.1.7.6 Naming a Data Module and Its Unit File

The title bar of a data module displays the module's name. The default name for a data module is "DataModule*N*" where *N* is a number representing the lowest unused unit number in a project. For example, if you start a new project, and add a module to it before doing any other application building, the name of the module defaults to "DataModule2." The corresponding unit file for *DataModule2* defaults to "Unit2."

You should rename your data modules and their corresponding unit files at design time to make them more descriptive. You should especially rename data modules you add to the Object Repository to avoid name conflicts with other data modules in the Repository or in applications that use your modules.

To rename a data module:

1. Select the module.

2. Edit the Name property for the module in the **Object Inspector**.

The new name for the module appears in the title bar when the *Name* property in the **Object Inspector** no longer has focus.

Changing the name of a data module at design time changes its variable name in the interface section of code. It also changes any use of the type name in procedure declarations. You must manually change any references to the data module in code you write.

To rename a unit file for a data module, select the unit file.

See Also

Designing Database Applications (see page 1566)

Creating and Editing Data Modules (see page 1911)

3.2.4.1.7.7 Placing and Naming Components

You place nonvisual components in a data module just as you place visual components on a form. Click the desired component on the appropriate category of the **Tool palette**, then click in the data module to place the component. You cannot place visual controls, such as grids, on a data module. If you attempt it, you receive an error message.

For ease of use, components are displayed with their names in a data module. When you first place a component, the module assigns it a generic name that identifies what kind of component it is, followed by a 1. For example, the *TDataSource* component adopts the name *DataSource1*. This makes it easy to select specific components whose properties and methods you want to work with.

You may still want to name a component a different name that reflects the type of component and what it is used for.

To change the name of a component in a data module:

1. Select the component.
2. Edit the component's *Name* property in the **Object Inspector**.

The new name for the component appears under its icon in the data module as soon as the *Name* property in the **Object Inspector** no longer has focus.

For example, suppose your database application uses the CUSTOMER table. To access the table, you need a minimum of two data access components: a data source component (*TDataSource*) and a table component (*TClientDataSet*). When you place these components in your data module, the module assigns them the names *DataSource1* and *ClientDataSet1*. To reflect the type of component and the database they access, CUSTOMER, you could change these names to *CustomerSource* and *CustomerTable*.

See Also

Designing Database Applications (see page 1566)

Creating and Editing Data Modules (see page 1911)

3.2.4.1.7.8 Using Component Properties and Events in a Data Module

Placing components in a data module centralizes their behavior for your entire application. For example, you can use the properties of dataset components, such as *TClientDataSet*, to control the data available to the data source components that use those datasets. Setting the *ReadOnly* property to *True* for a dataset prevents users from editing the data they see in a data-aware visual control on a form. You can also invoke the Fields editor for a dataset, by double-clicking on *ClientDataSet1*, to restrict the fields within a table or query that are available to a data source and therefore to the data-aware controls on forms. The properties you set for components in a data module apply consistently to all forms in your application that use the module.

In addition to properties, you can write event handlers for components. For example, a TDataSource component has three possible events: *OnDataChange*, *OnStateChange*, and *OnUpdateData*. A *TClientDataSet* component has over 20 potential events. You can use these events to create a consistent set of business rules that govern data manipulation throughout your

application.

Designing Database Applications (see page 1566)

Creating Business Rules in a Data Module (see page 1911)

3.2.4.1.8 Using the Object Repository

Topics

Name	Description
Adding Items to the Object Repository (see page 1915)	You can add your own projects, forms, frames, and data modules to those already available in the Object Repository.
Copying an Item (see page 1915)	Choose Copy to make an exact copy of the selected item and add the copy to your project. Future changes made to the item in the Object Repository will not be reflected in your copy, and alterations made to your copy will not affect the original Object Repository item. Copy is the only option available for project templates.
Inheriting an Item (see page 1915)	Choose Inherit to derive a new class from the selected item and add the new class to your project. When you recompile your project, any changes that have been made to the item Will be reflected in your derived class, in addition to changes you make to the item in your project. Changes made to your derived class do not affect the shared item in the Object Repository. Inherit is available for forms, dialog boxes, and data modules, but not for project templates. It is the *only* option available for reusing items within the same project.
Modifying Shared Items (see page 1916)	If you modify an item in the Object Repository, your changes will affect all future projects that use the item as well as existing projects that have added the item with the Use or Inherit option. To avoid propagating changes to other projects, you have several alternatives: • Copy the item and modify it in your current project only. • Copy the item to the current project, modify it, then add it to the Repository under a different name. • Create a component, DLL, component template, or frame from the item. If you create a component or DLL, you can share it with... more (see page 1916)
Sharing Items Within a Project (see page 1916)	You can share items *within* a project without adding them to the Object Repository. When you open the New Items dialog box (**File** ▶ **New** ▶ **Other**), you"ll see a page tab with the name of the current project. This page lists all the forms, dialog boxes, and data modules in the project. You can derive a new item from an existing item and customize it as needed.
Sharing Objects in a Team Environment (see page 1916)	You can share objects with your workgroup or development team by making a repository available over a network.
Using an Item (see page 1916)	Choose Use when you want the selected item itself to become part of your project. Changes made to the item in your project will appear in all other projects that have added the item with the Inherit or Use option. Select this option with caution. The Use option is available for forms, dialog boxes, and data modules.
Using an Object Repository Item in a Project (see page 1917)	To access items in the Object Repository, choose **File** ▶ **New** ▶ **Other**. The New Items dialog appears, showing all the items available. Depending on the type of item you want to use, you have up to three options for adding the item to your project: • Copy (see page 1915) • Inherit (see page 1915) • Use (see page 1916)
Using Project Templates (see page 1917)	Templates are predesigned projects that you can use as starting points for your own work.

Using the Object Repository (see page 1917)	The Object Repository (**Tools** ▶ **Options** ▶ **Repository (under Translation Tools Options)**) makes it easy share forms, dialog boxes, frames, and data modules. It also provides templates for new projects and wizards that guide the user through the creation of forms and projects. The Object Repository is maintained in DELPHI32.DRO (by default in the BIN directory), a text file that contains references to the items that appear in the Repository and New Items dialogs.

3.2.4.1.8.1 Adding Items to the Object Repository

You can add your own projects, forms, frames, and data modules to those already available in the Object Repository.

To add an item to the Object Repository

1. If the item is a project or is in a project, open the project.
2. For a project, choose **Project** ▶ **Add To Repository**. For a form or data module, right-click the item and choose Add To Repository.
3. Type a description, title, and author.
4. Decide which page you want the item to appear on in the New Items dialog box, then type the name of the page or select it from the Page combo box. If you type the name of a page that doesn't exist, the Object Repository creates a new page.
5. Choose Browse to select an icon to represent the object in the Object Repository.
6. Choose OK.

See Also

Using the Object Repository (see page 1917)

3.2.4.1.8.2 Copying an Item

Choose Copy to make an exact copy of the selected item and add the copy to your project. Future changes made to the item in the Object Repository will not be reflected in your copy, and alterations made to your copy will not affect the original Object Repository item.

Copy is the only option available for project templates.

See Also

Using an Object Repository Item in a Project (see page 1917)

Inheriting an Item (see page 1915)

Using an Item (see page 1916)

3.2.4.1.8.3 Inheriting an Item

Choose Inherit to derive a new class from the selected item and add the new class to your project. When you recompile your project, any changes that have been made to the item Will be reflected in your derived class, in addition to changes you make to the item in your project. Changes made to your derived class do not affect the shared item in the Object Repository.

Inherit is available for forms, dialog boxes, and data modules, but not for project templates. It is the *only* option available for reusing items within the same project.

See Also

Using an Object Repository Item in a Project (see page 1917)

Using an Item (see page 1916)

Copying an Item (see page 1915)

3.2.4.1.8.4 Modifying Shared Items

If you modify an item in the Object Repository, your changes will affect all future projects that use the item as well as existing projects that have added the item with the Use or Inherit option. To avoid propagating changes to other projects, you have several alternatives:

- Copy the item and modify it in your current project only.
- Copy the item to the current project, modify it, then add it to the Repository under a different name.
- Create a component, DLL, component template, or frame from the item. If you create a component or DLL, you can share it with other developers.

See Also

Using the Object Repository (see page 1917)

Copying an Item (see page 1915)

Adding Items to the Object Repository (see page 1915)

3.2.4.1.8.5 Sharing Items Within a Project

You can share items *within* a project without adding them to the Object Repository. When you open the New Items dialog box (**File** ▸ **New** ▸ **Other**), you"ll see a page tab with the name of the current project. This page lists all the forms, dialog boxes, and data modules in the project. You can derive a new item from an existing item and customize it as needed.

See Also

Using the Object Repository (see page 1917)

3.2.4.1.8.6 Sharing Objects in a Team Environment

You can share objects with your workgroup or development team by making a repository available over a network.

To use a shared repository, all team members must select the same Shared Repository directory in the Environment Options dialog:

1. Choose **Tools** ▸ **Options** ▸ **Environment Options**.
2. On the Preferences page, locate the Shared Repository panel. In the Directory edit box, enter the directory where you want to locate the shared repository. Be sure to specify a directory that's accessible to all team members.

The first time an item is added to the Repository, a DELPHI32.DRO file is created in the Shared Repository directory if one doesn't exist already.

See Also

Using the Object Repository (see page 1917)

3.2.4.1.8.7 Using an Item

Choose Use when you want the selected item itself to become part of your project. Changes made to the item in your project will appear in all other projects that have added the item with the Inherit or Use option. Select this option with caution.

The Use option is available for forms, dialog boxes, and data modules.

See Also

Using an Object Repository Item in a Project (see page 1917)

Copying an Item (see page 1915)

Inheriting an Item (see page 1915)

3.2.4.1.8.8 Using an Object Repository Item in a Project

To access items in the Object Repository, choose **File ▸ New ▸ Other**. The New Items dialog appears, showing all the items available. Depending on the type of item you want to use, you have up to three options for adding the item to your project:

- Copy (see page 1915)
- Inherit (see page 1915)
- Use (see page 1916)

See Also

Using the Object Repository (see page 1917)

3.2.4.1.8.9 Using Project Templates

Templates are predesigned projects that you can use as starting points for your own work.

To create a new project from a template:

1. Choose **File ▸ New ▸ Other** to display the New Items dialog box.
2. Choose the Projects tab.
3. Select the project template you want and choose OK.
4. In the Select Directory dialog, specify a directory for the new project's files.

The template files are copied to the specified directory, where you can modify them. The original project template is unaffected by your changes.

To add projects and project templates to the Object Repository, see Adding items to the Object Repository (see page 1915).

See Also

Using the Object Repository (see page 1917)

3.2.4.1.8.10 Using the Object Repository

The Object Repository (**Tools ▸ Options ▸ Repository (under Translation Tools Options)**) makes it easy share forms, dialog boxes, frames, and data modules. It also provides templates for new projects and wizards that guide the user through the creation of forms and projects. The Object Repository is maintained in DELPHI32.DRO (by default in the BIN directory), a text file that contains references to the items that appear in the Repository and New Items dialogs.

3.2.4.1.9 Writing applications using COM

Topics

Name	Description
Writing Applications Using COM (see page 1918)	COM is the Component Object Model, a Windows-based distributed object architecture designed to provide object interoperability using predefined routines called interfaces. COM applications use objects that are implemented by a different process or, if you use DCOM, on a separate machine. You can also use COM+, ActiveX and Active Server Pages. COM is a language-independent software component model that enables interaction between software components and applications running on a Windows platform. The key aspect of COM is that it enables communication between components, between applications, and between clients and servers through clearly defined interfaces. Interfaces provide a way for clients... more (see page 1918)

3.2.4.1.9.1 Writing Applications Using COM

COM is the Component Object Model, a Windows-based distributed object architecture designed to provide object interoperability using predefined routines called interfaces. COM applications use objects that are implemented by a different process or, if you use DCOM, on a separate machine. You can also use COM+, ActiveX and Active Server Pages.

COM is a language-independent software component model that enables interaction between software components and applications running on a Windows platform. The key aspect of COM is that it enables communication between components, between applications, and between clients and servers through clearly defined interfaces. Interfaces provide a way for clients to ask a COM component which features it supports at runtime. To provide additional features for your component, you simply add an additional interface for those features.

Using COM and DCOM

Various classes and wizards that make it easy to create COM, OLE, or ActiveX applications. You can create COM clients or servers that implement COM objects, Automation servers (including Active Server Objects), ActiveX controls, or ActiveForms. COM also severs as the basis for other technologies such as Automation, ActiveX controls, Active Documents, and Active Directories.

Using Delphi to create COM-based applications offers a wide range of possibilities, from improving software design by using interfaces internally in an application, to creating objects that can interact with other COM-based API objects on the system, such as the Win9x Shell extensions and DirectX multimedia support. Applications can access the interfaces of COM components that exist on the same computer as the application or that exist on another computer on the network using a mechanism called Distributed COM (DCOM).

For more information on COM and Active X controls, see Overview of COM technologies (see page 1385)Creating an ActiveX Control and Distributing a Client Application as an ActiveX Control (see page 1530).

For more information on DCOM, see Using DCOM connections (see page 1546).

Using MTS and COM+

COM applications can be augmented with special services for managing objects in a large distributed environment. These services include transaction services, security, and resource management supplied by Microsoft Transaction Server (MTS) on versions of Windows prior to Windows 2000) or COM+ (for Windows 2000 and later).

For more information on MTS and COM+, see Creating MTS or COM+ objects and Using transactional data modules (see page 1546).

3.2.4.1.10 Writing database applications

Topics

Name	Description
Distributing Database Applications (see page 1919)	You can create distributed database applications using a coordinated set of components. Distributed database applications can be built on a variety of communications protocols, including DCOM, TCP/IP, and SOAP. For more information about building distributed database applications, see Creating Multi-tiered Applications. (see page 1518) Distributing database applications often requires you to distribute the Borland Database Engine (BDE) in addition to the application files. For information on deploying the BDE, see Deploying Database Applications. (see page 1948)
Writing Database Applications (see page 1919)	You can create advanced database applications using tools to connect to SQL servers and databases such as Oracle, Sybase, InterBase, MySQL, MS-SQL, Informix, PostgreSQL, and DB2 while providing transparent data sharing between applications. The **Tool palette** includes many components for accessing databases and representing the information they contain. The database components are grouped according to the data access mechanism and function. ***Database pages on the Tool palette***

3.2.4.1.10.1 Distributing Database Applications

You can create distributed database applications using a coordinated set of components. Distributed database applications can be built on a variety of communications protocols, including DCOM, TCP/IP, and SOAP.

For more information about building distributed database applications, see Creating Multi-tiered Applications. (see page 1518)

Distributing database applications often requires you to distribute the Borland Database Engine (BDE) in addition to the application files. For information on deploying the BDE, see Deploying Database Applications. (see page 1948)

TDataSet

TDatabase

3.2.4.1.10.2 Writing Database Applications

You can create advanced database applications using tools to connect to SQL servers and databases such as Oracle, Sybase, InterBase, MySQL, MS-SQL, Informix, PostgreSQL, and DB2 while providing transparent data sharing between applications.

The **Tool palette** includes many components for accessing databases and representing the information they contain. The database components are grouped according to the data access mechanism and function.

Database pages on the Tool palette

Palette page	Contents
BDE	Components that use the Borland Database Engine (BDE), a large API for interacting with databases. The BDE supports the broadest range of functions and comes with the most supporting utilities including Database Desktop and Database Explorer . See Using the Borland Database Engine (see page 1643) for details.
ADO	Components that use ActiveX Data Objects (ADO), developed by Microsoft, to access database information. Many ADO drivers are available for connecting to different database servers. ADO-based components let you integrate your application into an ADO-based environment. See Working with ADO Components (see page 1494) for details.

dbExpress	Cross-platform components that use dbExpress to access database information. dbExpress drivers provide fast access to databases but need to be used with *TClientDataSet* and *TDataSetProvider* to perform updates. See Using Unidirectional Datasets (see page 1823) for details.
InterBase	Components that access InterBase databases directly, without going through a separate engine layer.
Data Access	Components that can be used with any data access mechanism such as *TClientDataSet* and *TDataSetProvider*. See Using Client Datasets: Overview (see page 1740) for information about client datasets. See Using Provider Components (see page 1819) for information about providers.
Data Controls	Data-aware controls that can access information from a data source. See Using Data Controls (see page 1778) for details.

When designing a database application, you must decide which data access mechanism to use. Each data access mechanism differs in its range of functional support, the ease of deployment, and the availability of drivers to support different database servers.

Refer to Designing database applications (see page 1566) for details on what type of database support is available and considerations when designing database client applications and application servers.

Note: Not all editions of Delphi include database support.

3.2.4.2 Creating international applications

Topics

Name	Description
Creating International Applications: Overview (see page 1923)	This topic discusses guidelines for writing applications that you plan to distribute to an international market. By planning ahead, you can reduce the amount of time and code necessary to make your application function in its foreign market as well as in its domestic market. The following topics are discussed in this section: • Internationalization and localization (see page 1923) • Internationalizing applications (see page 1924) • Localizing applications (see page 1934)
Internationalization and Localization (see page 1923)	To create an application that you can distribute to foreign markets, there are two major steps that need to be performed: • Internationalization (see page 1923) • Localization (see page 1924) If your edition includes the Translation Tools, you can use the them to manage localization.
Internationalization (see page 1923)	Internationalization is the process of enabling your program to work in multiple locales. A locale is the user's environment, which includes the cultural conventions of the target country as well as the language. Windows supports many locales, each of which is described by a language and country pair.
Localization (see page 1924)	Localization is the process of translating an application so that it functions in a specific locale. In addition to translating the user interface, localization may include functionality customization. For example, a financial application may be modified for the tax laws in different countries.

Internationalizing Applications (see page 1924)	You need to complete the following steps to create internationalized applications: • Enable your code (see page 1924) to handle strings from international character sets. • Design your user interface (see page 1929) to accommodate the changes that result from localization. • Isolate all resources (see page 1931) that need to be localized.
Enabling Application Code (see page 1924)	You must make sure that the code in your application can handle the strings it will encounter in the various target locales. To do this, you must consider the following: • Character sets (see page 1924) • OEM and ANSI character sets (see page 1925) • Multibyte character sets (see page 1925) • Wide characters • Locale-specific features (see page 1928)
Character Sets (see page 1924)	The Western editions (including English, French, and German) of Windows use the ANSI Latin-1 (1252) character set. However, other editions of Windows use different character sets. For example, the Japanese version of Windows uses the Shift-JIS character set (code page 932), which represents Japanese characters as multibyte character codes. There are generally three types of characters sets: • Single-byte • Multibyte • Wide characters Windows and Linux both support single-byte and multibyte character sets as well as Unicode. With a single-byte character set, each byte in a string represents one character. The ANSI character set used by many western operating systems is a... more (see page 1924)
OEM and ANSI Character Sets (see page 1925)	It is sometimes necessary to convert between the Windows character set (ANSI) and the character set specified by the code page of the user's machine (called the OEM character set).
Multibyte Character Sets (MBCS) (see page 1925)	The ideographic character sets used in Asia cannot use the simple 1:1 mapping between characters in the language and the one byte (8-bit) **AnsiChar** type. These languages have too many characters to be represented using the single-byte **AnsiChar**. Instead, a multibyte character set string can contain one or more bytes per character. A multibyte character set provides a way to encode characters outside the standard ANSI range into single byte strings of **AnsiChar**. The lead byte of every multibyte character code is taken from a reserved range that depends on the specific character set. The second and subsequent... more (see page 1925)
Including Bi-directional Functionality in Applications (see page 1926)	Some languages do not follow the left to right reading order commonly found in western languages, but rather read words right to left and numbers left to right. These languages are termed bi-directional (BiDi) because of this separation. The most common bi-directional languages are Arabic and Hebrew, although other Middle East languages are also bi-directional. *TApplication* has two properties, *BiDiKeyboard* and *NonBiDiKeyboard*, that allow you to specify the keyboard layout. In addition, the VCL supports bi-directional localization through the *BiDiMode* and *ParentBiDiMode* properties. **Note:** Bi-directional properties are not available for cross-platform applications. The BiDiMode property controls the reading order... more (see page 1926)
ParentBiDiMode Property (see page 1927)	*ParentBiDiMode* is a Boolean property. When *True* (the default) the control looks to its parent to determine what *BiDiMode* to use. If the control is a *TForm* object, the form uses the *BiDiMode* setting from Application. If all the *ParentBiDiMode* properties are *True*, when you change Application's *BiDiMode* property, all forms and controls in the project are updated with the new setting.

FlipChildren Method (see page 1927)	The *FlipChildren* method allows you to flip the position of a container control's children. Container controls are controls that can accept other controls, such as *TForm*, *TPanel*, and *TGroupBox*.*FlipChildren* has a single boolean parameter, *AllLevels*. When *False*, only the immediate children of the container control are flipped. When *True*, all the levels of children in the container control are flipped. Delphi flips the controls by changing the Left property and the alignment of the control. If a control's left side is five pixels from the left edge of its parent control, after it is flipped... more (see page 1927)
Additional Methods (see page 1928)	There are several other methods useful for developing applications for bi-directional users. ***VCL methods that support BiDi***
Locale-specific Features (see page 1928)	You can add extra features to your application for specific locales. In particular, for Asian language environments, you may want your application to control the input method editor (IME) that is used to convert the keystrokes typed by the user into character strings. Controls offer support in programming the IME. Most windowed controls that work directly with text input have an ImeName property that allows you to specify a particular IME that should be used when the control has input focus. They also provide an ImeMode property that specifies how the IME should convert keyboard input. ImeName introduces several... more (see page 1928)
Localization Considerations in UI Design (see page 1929)	When creating an application for several foreign markets, it is important to design your user interface so that it can accommodate the changes that occur during translation. The following topics are discussed in this section: • Text (see page 1929) • Graphic images (see page 1930) • Formats and sort order (see page 1930) • Keyboard mappings (see page 1931)
Text (see page 1929)	All text that appears in the user interface must be translated. English text is almost always shorter than its translations. Design the elements of your user interface that display text so that there is room for the text strings to grow. Create dialogs, menus, status bars, and other user interface elements that display text so that they can easily display longer strings. Avoid abbreviations—they do not exist in languages that use ideographic characters. Short strings tend to grow in translation more than long phrases. The following table provides a rough estimate of how much expansion you should plan for given... more (see page 1929)
Graphic Images (see page 1930)	Ideally, you will want to use images that do not require translation. Most obviously, this means that graphic images should not include text, which will always require translation. If you must include text in your images, it is a good idea to use a label object with a transparent background over an image rather than including the text as part of the image. There are other considerations when creating graphic images. Try to avoid images that are specific to a particular culture. For example, mailboxes in different countries look very different from each other. Religious symbols are not appropriate if... more (see page 1930)
Formats and Sort Order (see page 1930)	The date, time, number, and currency formats used in your application should be localized for the target locale. If you use only the Windows formats, there is no need to translate formats, as these are taken from the user's Windows Registry. However, if you specify any of your own format strings, be sure to declare them as resourced constants so that they can be localized. The order in which strings are sorted also varies from country to country. Many European languages include diacritical marks that are sorted differently, depending on the locale. In addition, in some countries, two-character... more (see page 1930)
Keyboard Mappings (see page 1931)	Be careful with key-combinations shortcut assignments. Not all the characters available on the US keyboard are easily reproduced on all international keyboards. Where possible, use number keys and function keys for shortcuts, as these are available on virtually all keyboards.
Isolating Resources (see page 1931)	The most obvious task in localizing an application is translating the strings that appear in the user interface. To create an application that can be translated without altering code everywhere, the strings in the user interface should be isolated into a single module. Delphi automatically creates a .dfm file that contains the resources for your menus, dialogs, and bitmaps. In addition to these obvious user interface elements, you will need to isolate any strings, such as error messages, that you present to the user. String resources are not included in the form file. You can isolate them by declaring constants... more (see page 1931)

Creating Resource DLLs (see page 1931)	Isolating resources simplifies the translation process. The next level of resource separation is the creation of a resource DLL. A resource DLL contains all the resources and only the resources for a program. Resource DLLs allow you to create a program that supports many translations simply by swapping the resource DLL. Use the Resource DLL wizard to create a resource DLL for your program. The Resource DLL wizard requires an open, saved, compiled project. It will create an RC file that contains the string tables from used RC files and **resourcestring** strings of the project, and generate a project for... more (see page 1931)
Using Resource DLLs (see page 1933)	The executable, DLLs, and packages (bpls) that make up your application contain all the necessary resources. However, to replace those resources by localized versions, you need only ship your application with localized resource DLLs that have the same name as your executable, DLL, or package files. When your application starts up, it checks the locale of the local system. If it finds any resource DLLs with the same name as the EXE, DLL, or BPL files it is using, it checks the extension on those DLLs. If the extension of the resource module matches the language and country of the... more (see page 1933)
Dynamic Switching of Resource DLLs (see page 1934)	In addition to locating a resource DLL at application startup, it is possible to switch resource DLLs dynamically at runtime. To add this functionality to your own applications, you need to include the ReInit unit in your **uses** statement. (ReInit is located in the Richedit sample in the Demos directory.) To switch languages, you should call *LoadResourceModule*, passing the LCID for the new language, and then call *ReinitializeForms*. For example, the following code switches the interface language to French:
Localizing Applications (see page 1934)	Once your application is internationalized, you can create localized versions for the different foreign markets in which you want to distribute it.

3.2.4.2.1 Creating International Applications: Overview

This topic discusses guidelines for writing applications that you plan to distribute to an international market. By planning ahead, you can reduce the amount of time and code necessary to make your application function in its foreign market as well as in its domestic market.

The following topics are discussed in this section:

- Internationalization and localization (see page 1923)
- Internationalizing applications (see page 1924)
- Localizing applications (see page 1934)

See Also

Deploying Applications (see page 1947)

3.2.4.2.2 Internationalization and Localization

To create an application that you can distribute to foreign markets, there are two major steps that need to be performed:

- Internationalization (see page 1923)
- Localization (see page 1924)

If your edition includes the Translation Tools, you can use the them to manage localization.

See Also

Internationalizing Applications (see page 1924)

Localizing Applications (see page 1934)

3.2.4.2.3 Internationalization

Internationalization is the process of enabling your program to work in multiple locales. A locale is the user's environment, which includes the cultural conventions of the target country as well as the language. Windows supports many locales, each of which is

described by a language and country pair.

Internationalization (see page 1923)

Localizing Applications (see page 1934)

3.2.4.2.5 Internationalizing Applications

You need to complete the following steps to create internationalized applications:

- Enable your code (see page 1924) to handle strings from international character sets.
- Design your user interface (see page 1929) to accommodate the changes that result from localization.
- Isolate all resources (see page 1931) that need to be localized.

See Also

Internationalization (see page 1923)

Localizing Applications (see page 1934)

3.2.4.2.6 Enabling Application Code

You must make sure that the code in your application can handle the strings it will encounter in the various target locales. To do this, you must consider the following:

- Character sets (see page 1924)
- OEM and ANSI character sets (see page 1925)
- Multibyte character sets (see page 1925)
- Wide characters
- Locale-specific features (see page 1928)

See Also

Designing the User Interface (see page 1929)

Isolating Resources (see page 1931)

3.2.4.2.7 Character Sets

The Western editions (including English, French, and German) of Windows use the ANSI Latin-1 (1252) character set. However, other editions of Windows use different character sets. For example, the Japanese version of Windows uses the Shift-JIS character set (code page 932), which represents Japanese characters as multibyte character codes.

There are generally three types of characters sets:

- Single-byte
- Multibyte
- Wide characters

Windows and Linux both support single-byte and multibyte character sets as well as Unicode. With a single-byte character set, each byte in a string represents one character. The ANSI character set used by many western operating systems is a single-byte character set.

In a multibyte character set, some characters are represented by one byte and others by more than one byte. The first byte of a multibyte character is called the lead byte. In general, the lower 128 characters of a multibyte character set map to the 7-bit ASCII characters, and any byte whose ordinal value is greater than 127 is the lead byte of a multibyte character. Only single-byte characters can contain the null value (#0). Multibyte character sets—especially double-byte character sets (DBCS)—are widely used for Asian languages.

OEM and ANSI Character Sets (see page 1925)

Multibyte Character Sets (see page 1925)

Locale-specific Features (see page 1928)

Wide Characters

Unicode in RAD Studio

Enabling Unicode in Your Applications

3.2.4.2.8 OEM and ANSI Character Sets

It is sometimes necessary to convert between the Windows character set (ANSI) and the character set specified by the code page of the user's machine (called the OEM character set).

See Also

Character Sets (see page 1924)

Multibyte Character Sets (see page 1925)

Locale-specific Features (see page 1928)

Wide Characters

3.2.4.2.9 Multibyte Character Sets (MBCS)

The ideographic character sets used in Asia cannot use the simple 1:1 mapping between characters in the language and the one byte (8-bit) **AnsiChar** type. These languages have too many characters to be represented using the single-byte **AnsiChar**. Instead, a multibyte character set string can contain one or more bytes per character. A multibyte character set provides a way to encode characters outside the standard ANSI range into single byte strings of **AnsiChar**.

The lead byte of every multibyte character code is taken from a reserved range that depends on the specific character set. The second and subsequent bytes can sometimes be the same as the character code for a separate one-byte character, or it can fall in the range reserved for the first byte of multibyte characters. Thus, the only way to tell whether a particular byte in a string represents a single character or is part of a multibyte character is to read the string, starting at the beginning, parsing it into two or more byte characters when a lead byte from the reserved range is encountered.

When writing code for Asian locales, you must be sure to handle all string manipulation using functions that are enabled to parse strings into multibyte characters.

For these reasons, you cannot process multibyte character strings (MBCS) as you process single byte character strings. You should use a string type appropriate for MCBS data, such as **AnsiString** or a short string.

Delphi provides you with many of these runtime library functions, as listed in the following table:

Runtime library functions

AdjustLineBreaks	AnsiStrLower	ExtractFileDir
AnsiCompareFileName	AnsiStrPos	ExtractFileExt
AnsiExtractQuotedStr	AnsiStrRScan	ExtractFileName
AnsiLastChar	AnsiStrScan	ExtractFilePath
AnsiLowerCase	AnsiStrUpper	ExtractRelativePath
AnsiLowerCaseFileName	AnsiUpperCase	FileSearch
AnsiPos	AnsiUpperCaseFileName	IsDelimiter
AnsiQuotedStr	ByteToCharIndex	IsPathDelimiter
AnsiStrComp	ByteToCharLen	LastDelimiter
AnsiStrIComp	ByteType	StrByteType
AnsiStrLastChar	ChangeFileExt	StringReplace
AnsiStrLComp	CharToByteIndex	WrapText
AnsiStrLIComp	CharToByteLen	

Remember that the length of the strings in bytes does not necessarily correspond to the length of the string in characters. Be careful not to truncate strings by cutting a multibyte character in half. Do not pass characters as a parameter to a function or procedure, since the size of a character can't be known up front. Instead, always pass a pointer to a character or a string.

Ideographic character sets can also be represented in Unicode with the **UnicodeString** or **WideString** types. The **WideString** character type is essentially the same as a Windows BSTR. **WideString** is still appropriate for use in COM applications. However, **WideString** is not reference counted, and **UnicodeString** is more flexible and efficient in other types of applications. In addition, more functions are available for handling **UnicodeString** types than **WideString**, so **UnicodeString** is generally preferred.

Enabling Unicode in Your Applications

Unicode in RAD Studio

3.2.4.2.10 Including Bi-directional Functionality in Applications

Some languages do not follow the left to right reading order commonly found in western languages, but rather read words right to left and numbers left to right. These languages are termed bi-directional (BiDi) because of this separation. The most common bi-directional languages are Arabic and Hebrew, although other Middle East languages are also bi-directional.

TApplication has two properties, *BiDiKeyboard* and *NonBiDiKeyboard*, that allow you to specify the keyboard layout. In addition, the VCL supports bi-directional localization through the *BiDiMode* and *ParentBiDiMode* properties.

Note: Bi-directional properties are not available for cross-platform applications.

The BiDiMode property controls the reading order for the text, the placement of the vertical scrollbar, and whether the alignment is changed. Controls that have a text property, such as *Name*, display the *BiDiMode* property on the **Object Inspector**.

The *BiDiMode* property is a new enumerated type, *TBiDiMode*, with four states: *bdLeftToRight*, *bdRightToLeft*, *bdRightToLeftNoAlign*, and *bdRightToLeftReadingOnly*.

bdLeftToRight

bdLeftToRight draws text using left to right reading order. The alignment and scroll bars are not changed. For instance, when entering right to left text, such as Arabic or Hebrew, the cursor goes into push mode and the text is entered right to left. Latin text, such as English or French, is entered left to right. *bdLeftToRight* is the default value.

bdRightToLeft

bdRightToLeft draws text using right to left reading order, the alignment is changed and the scroll bar is moved. Text is entered as normal for right-to-left languages such as Arabic or Hebrew. When the keyboard is changed to a Latin language, the cursor goes into push mode and the text is entered left to right.

bdRightToLeftNoAlign

bdRightToLeftNoAlign draws text using right to left reading order, the alignment is not changed, and the scroll bar is moved.

bdRightToLeftReadingOnly

bdRightToLeftReadingOnly draws text using right to left reading order, and the alignment and scroll bars are not changed.

See Also

Localization (see page 1924)

Internationalizing Applications (see page 1924)

3.2.4.2.11 ParentBiDiMode Property

ParentBiDiMode is a Boolean property. When *True* (the default) the control looks to its parent to determine what *BiDiMode* to use. If the control is a *TForm* object, the form uses the *BiDiMode* setting from Application. If all the *ParentBiDiMode* properties are *True*, when you change Application's *BiDiMode* property, all forms and controls in the project are updated with the new setting.

See Also

Localization (see page 1924)

Internationalizing Applications (see page 1924)

3.2.4.2.12 FlipChildren Method

The *FlipChildren* method allows you to flip the position of a container control's children. Container controls are controls that can accept other controls, such as *TForm*, *TPanel*, and *TGroupBox*.*FlipChildren* has a single boolean parameter, *AllLevels*. When *False*, only the immediate children of the container control are flipped. When *True*, all the levels of children in the container control are flipped.

Delphi flips the controls by changing the Left property and the alignment of the control. If a control's left side is five pixels from the left edge of its parent control, after it is flipped the edit control's right side is five pixels from the right edge of the parent control. If the edit control is left aligned, calling *FlipChildren* will make the control right aligned.

To flip a control at design-time select **Edit ▸ Flip Children** and select either All or Selected, depending on whether you want to flip all the controls, or just the children of the selected control. You can also flip a control by selecting the control on the form, right-clicking, and selecting Flip Children from the context menu.

Note: Selecting an edit control and issuing a Flip Children|Selected command does nothing. This is because edit controls are not containers.

Localization (see page 1924)

Internationalizing Applications (see page 1924)

Additional Methods (see page 1928)

3.2.4.2.13 Additional Methods

There are several other methods useful for developing applications for bi-directional users.

VCL methods that support BiDi

Method	Description
OkToChangeFieldAlignment	Used with database controls. Checks to see if the alignment of a control can be changed.
DBUseRightToLeftAlignment	A wrapper for database controls for checking alignment.
ChangeBiDiModeAlignment	Changes the alignment parameter passed to it. No check is done for *BiDiMode* setting, it just converts left alignment into right alignment and vice versa, leaving center-aligned controls alone.
IsRightToLeft	Returns *True* if any of the right to left options are selected. If it returns *False* the control is in left to right mode.
UseRightToLeftReading	Returns *True* if the control is using right to left reading.
UseRightToLeftAlignment	Returns *True* if the control is using right to left alignment. It can be overridden for customization.
UseRightToLeftScrollBar	Returns *True* if the control is using a left scroll bar.
DrawTextBiDiModeFlags	Returns the correct draw text flags for the *BiDiMode* of the control.
DrawTextBiDiModeFlagsReadingOnly	Returns the correct draw text flags for the *BiDiMode* of the control, limiting the flag to its reading order.
AddBiDiModeExStyle	Adds the appropriate *ExStyle* flags to the control that is being created.

FlipChildren Method (see page 1927)

3.2.4.2.14 Locale-specific Features

You can add extra features to your application for specific locales. In particular, for Asian language environments, you may want your application to control the input method editor (IME) that is used to convert the keystrokes typed by the user into character strings.

Controls offer support in programming the IME. Most windowed controls that work directly with text input have an ImeName

property that allows you to specify a particular IME that should be used when the control has input focus. They also provide an ImeMode property that specifies how the IME should convert keyboard input. ImeName introduces several protected methods that you can use to control the IME from classes you define. In addition, the global Screen variable provides information about the IMEs available on the user's system.

The global *Screen* variable also provides information about the keyboard mapping installed on the user's system. You can use this to obtain locale-specific information about the environment in which your application is running.

The IME is available in VCL applications only.

Multibyte Character Sets (see page 1925)

3.2.4.2.15 Localization Considerations in UI Design

When creating an application for several foreign markets, it is important to design your user interface so that it can accommodate the changes that occur during translation.

The following topics are discussed in this section:

- Text (see page 1929)
- Graphic images (see page 1930)
- Formats and sort order (see page 1930)
- Keyboard mappings (see page 1931)

See Also

Enabling Application Code (see page 1924)

Isolating Resources (see page 1931)

Programming for Varying Host Environments (see page 1953)

3.2.4.2.16 Text

All text that appears in the user interface must be translated. English text is almost always shorter than its translations. Design the elements of your user interface that display text so that there is room for the text strings to grow. Create dialogs, menus, status bars, and other user interface elements that display text so that they can easily display longer strings. Avoid abbreviations—they do not exist in languages that use ideographic characters.

Short strings tend to grow in translation more than long phrases. The following table provides a rough estimate of how much expansion you should plan for given the length of your English strings:

Estimating string lengths

Length of English String (in characters)	Expected Increase
1-5	100%
6-12	80%
13-20	60%

21-30	40%
31-50	20%
over 50	10%

Graphic Images (see page 1930)

Formats and Sort Order (see page 1930)

Keyboard Mappings (see page 1931)

Working with String Lists (see page 2140)

3.2.4.2.17 Graphic Images

Ideally, you will want to use images that do not require translation. Most obviously, this means that graphic images should not include text, which will always require translation. If you must include text in your images, it is a good idea to use a label object with a transparent background over an image rather than including the text as part of the image.

There are other considerations when creating graphic images. Try to avoid images that are specific to a particular culture. For example, mailboxes in different countries look very different from each other. Religious symbols are not appropriate if your application is intended for countries that have different dominant religions. Even color can have different symbolic connotations in different cultures.

Text (see page 1929)

Formats and Sort Order (see page 1930)

Keyboard Mappings (see page 1931)

Adding Graphics to Controls (see page 2154)

Working With Graphics And Multi Media (see page 2208)

3.2.4.2.18 Formats and Sort Order

The date, time, number, and currency formats used in your application should be localized for the target locale. If you use only the Windows formats, there is no need to translate formats, as these are taken from the user's Windows Registry. However, if you specify any of your own format strings, be sure to declare them as resourced constants so that they can be localized.

The order in which strings are sorted also varies from country to country. Many European languages include diacritical marks that are sorted differently, depending on the locale. In addition, in some countries, two-character combinations are treated as a single character in the sort order. For example, in Spanish, the combination *ch* is sorted like a single unique letter between *c* and *d*. Sometimes a single character is sorted as if it were two separate characters, such as the German *eszett*.

Text (see page 1929)

Graphic Images (see page 1930)

Keyboard Mappings (see page 1931)

Character Sets (see page 1924)

3.2.4.2.19 Keyboard Mappings

Be careful with key-combinations shortcut assignments. Not all the characters available on the US keyboard are easily reproduced on all international keyboards. Where possible, use number keys and function keys for shortcuts, as these are available on virtually all keyboards.

3.2.4.2.20 Isolating Resources

The most obvious task in localizing an application is translating the strings that appear in the user interface. To create an application that can be translated without altering code everywhere, the strings in the user interface should be isolated into a single module. Delphi automatically creates a .dfm file that contains the resources for your menus, dialogs, and bitmaps.

In addition to these obvious user interface elements, you will need to isolate any strings, such as error messages, that you present to the user. String resources are not included in the form file. You can isolate them by declaring constants for them using the **resourcestring** keyword. For more information about resource string constants, see the *Delphi Language Guide*. It is best to include all resource strings in a single, separate unit.

For information on using resource DLLs in your applications see Creating Resource DLLs (see page 1931) and Using Resource DLLs (see page 1933).

See Also

Enabling Application Code (see page 1924)

Designing the User Interface (see page 1929)

Using Forms (see page 1990)

Creating Resource DLLs (see page 1931)

3.2.4.2.21 Creating Resource DLLs

Isolating resources simplifies the translation process. The next level of resource separation is the creation of a resource DLL. A resource DLL contains all the resources and only the resources for a program. Resource DLLs allow you to create a program that supports many translations simply by swapping the resource DLL.

Use the Resource DLL wizard to create a resource DLL for your program. The Resource DLL wizard requires an open, saved, compiled project. It will create an RC file that contains the string tables from used RC files and **resourcestring** strings of the project, and generate a project for a resource only DLL that contains the relevant forms and the created RES file. The RES file is compiled from the new RC file.

You should create a resource DLL for each translation you want to support. Each resource DLL should have a file name extension specific to the target locale. The first two characters indicate the target language, and the third character indicates the country of the locale. If you use the Resource DLL wizard, this is handled for you. Otherwise, use the following code to obtain the locale code for the target translation:

```
unit locales;
```

```
interface
uses
  Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs,
  StdCtrls;
type
  TForm1 = class(TForm)
    Button1: TButton;
    LocaleList: TListBox;
    procedure Button1Click(Sender: TObject);
  private
    { Private declarations }
  public
    { Public declarations }
  end;
var
  Form1: TForm1;
implementation
{$R *.DFM}
function GetLocaleData(ID: LCID; Flag: DWORD): string;
var
  BufSize: Integer;
begin
  BufSize := GetLocaleInfo(ID, Flag, nil, 0);
  SetLength(Result, BufSize);
  GetLocaleinfo(ID, Flag, PChar(Result), BufSize);
  SetLength(Result, BufSize - 1);
end;
{ Called for each supported locale. }
function LocalesCallback(Name: PChar): Bool; stdcall;
var
  LCID: Integer;
begin
  LCID := StrToInt('$' + Copy(Name, 5, 4));
  Form1.LocaleList.Items.Add(GetLocaleData(LCID, LOCALE_SLANGUAGE));
  Result := Bool(1);
end;
procedure TForm1.Button1Click(Sender: TObject);
var
  I: Integer;
begin
  with Languages do
  begin
    for I := 0 to Count - 1 do
    begin
      ListBox1.Items.Add(Name[I]);
    end;
  end;
end;
/* This callback fills a listbox with the strings and their associated languages and
countries*/
BOOL __stdcall EnumLocalesProc(char* lpLocaleString)
{
AnsiString LocaleName, LanguageName, CountryName;
LCID lcid;
lcid = StrToInt("$" + AnsiString(lpLocaleString));
LocaleName = GetLocaleStr(lcid, LOCALE_SABBREVLANGNAME, "");
LanguageName = GetLocaleStr(lcid, LOCALE_SNATIVELANGNAME, "");
CountryName = GetLocaleStr(lcid, LOCALE_SNATIVECTRYNAME, "");
if (lstrlen(LocaleName.c_str()) > 0)
Form1->ListBox1->Items->Add(LocaleName + ":" + LanguageName + "-" + CountryName);
return TRUE;
}
/* This call causes the callback to execute for every locale */
EnumSystemLocales((LOCALE_ENUMPROC)EnumLocalesProc, LCID_SUPPORTED);
```

Using Resource DLLs (see page 1933)

3.2.4.2.22 Using Resource DLLs

The executable, DLLs, and packages (bpls) that make up your application contain all the necessary resources. However, to replace those resources by localized versions, you need only ship your application with localized resource DLLs that have the same name as your executable, DLL, or package files.

When your application starts up, it checks the locale of the local system. If it finds any resource DLLs with the same name as the EXE, DLL, or BPL files it is using, it checks the extension on those DLLs. If the extension of the resource module matches the language and country of the system locale, your application will use the resources in that resource module instead of the resources in the executable, DLL, or package. If there is not a resource module that matches both the language and the country, your application will try to locate a resource module that matches just the language. If there is no resource module that matches the language, your application will use the resources compiled with the executable, DLL, or package.

If you want your application to use a different resource module than the one that matches the locale of the local system, you can set a locale override entry in the Windows registry. Under the HKEY_CURRENT_USER\Software\Borland\Locales key, add your application's path and file name as a string value and set the data value to the extension of your resource DLLs. At startup, the application will look for resource DLLs with this extension before trying the system locale. Setting this registry entry allows you to test localized versions of your application without changing the locale on your system.

For example, the following procedure can be used in an install or setup program to set the registry key value that indicates the locale to use when loading applications:

```
procedure SetLocalOverrides(FileName: string, LocaleOverride: string);
var
Reg: TRegistry;
begin
Reg := TRegistry.Create;
try
if Reg.OpenKey('Software\Borland\Locales', True) then
Reg.WriteString(LocalOverride, FileName);
finally
Reg.Free;
  end;
end;
void SetLocalOverrides(char* FileName, char* LocaleOverride)
{
HKEY Key;
const char* LocaleOverrideKey = "Software\\Borland\\Locales";
if (RegOpenKeyEx(HKEY_CURRENT_USER, LocaleOverrideKey, 0, KEY_ALL_ACCESS, &Key)
== ERROR_SUCCESS) {
if (lstrlen(LocaleOverride) == 3)
RegSetValueEx(Key, FileName, 0, REG_SZ, (const BYTE*)LocaleOverride, 4);
RegCloseKey(Key);
}
}
```

Within your application, use the global *FindResourceHInstance* function to obtain the handle of the current resource module. For example:

```
LoadStr(FindResourceHInstance(HInstance), IDS_AmountDueName, szQuery, SizeOf(szQuery));
LoadString(FindResourceHInstance(HInstance), IDS_AmountDueName, szQuery, sizeof(szQuery));
```

You can ship a single application that adapts itself automatically to the locale of the system it is running on, simply by providing the appropriate resource DLLs.

See Also

Creating Resource DLLs (see page 1931)

3.2.4.2.23 Dynamic Switching of Resource DLLs

In addition to locating a resource DLL at application startup, it is possible to switch resource DLLs dynamically at runtime. To add this functionality to your own applications, you need to include the ReInit unit in your **uses** statement. (ReInit is located in the Richedit sample in the Demos directory.) To switch languages, you should call *LoadResourceModule*, passing the LCID for the new language, and then call *ReinitializeForms*.

For example, the following code switches the interface language to French:

```
const
  FRENCH = (SUBLANG_FRENCH shl 10) or LANG_FRENCH;
if LoadNewResourceModule(FRENCH) <> 0 then
  ReinitializeForms;
const  FRENCH = MAKELANGID(SUBLANG_FRENCH, LANG_FRENCH);
if (LoadNewResourceModule(FRENCH))
  ReinitializeForms();
```

The advantage of this technique is that the current instance of the application and all of its forms are used. It is not necessary to update the registry settings and restart the application or re-acquire resources required by the application, such as logging in to database servers.

When you switch resource DLLs the properties specified in the new DLL overwrite the properties in the running instances of the forms.

Note: Any changes made to the form properties at runtime will be lost. Once the new DLL is loaded, default values are not reset. Avoid code that assumes that the form objects are reinitialized to the their startup state, apart from differences due to localization.

See Also

Creating Resource DLLs (see page 1931)

3.2.4.2.24 Localizing Applications

Once your application is internationalized, you can create localized versions for the different foreign markets in which you want to distribute it.

Localizing resources

Ideally, your resources have been isolated into a resource DLL that contains form files (.dfm in VCL applications) and a resource file. You can open your forms in the IDE and translate the relevant properties.

Note: In a resource DLL project, you cannot add or delete components. It is possible, however, to change properties in ways that could cause runtime errors, so be careful to modify only those properties that require translation. To avoid mistakes, you can configure the Object Inspector

to display only Localizable properties; to do so, right-click in the **Object Inspector** and use the View menu to filter out unwanted property categories. You can open the RC file and translate relevant strings. Use the StringTable editor by opening the RC file from the **Project Manager**.

TeamSource software (not available in all editions) is also available for tracking application updates. **Note:** Not all editions have deployment capabilities. Refer to Deploying Applications (see page 1947) for specific information on deployment.

3.2.4.3.1 Designing Applications

You can design any kind of 32-bit applicationfrom general—purpose utilities to sophisticated data access programs or distributed applications.

As you visually design the user interface for your application, the Form Designer generates the underlying Delphi code to support the application. As you select and modify the properties of components and forms, the results of those changes appear automatically in the source code, and vice versa. You can modify the source files directly with any text editor, including the built-in Code editor. The changes you make are immediately reflected in the visual environment.

You can create your own components using the Delphi language. Most of the components provided are written in Delphi. You can add components that you write to the **Tool palette** and customize the palette for your use by including new tabs if needed.

Creating applications (see page 1883) introduces support for different types of applications.

See Also

Developing the Application User Interface: Overview (see page 1983)

Working with Components (see page 2142)

Creating and Managing Menus (see page 1975)

3.2.4.3.2 Creating Projects

All application development revolves around projects. When you create an application in Delphi you are creating a project. A project is a collection of files that make up an application. Some of these files are created at design time. Others are generated automatically when you compile the project source code.

You can view the contents of a project in a project management tool called the **Project Manager**. The **Project Manager** lists, in a hierarchical view, the unit names, the forms contained in the unit (if there is one), and shows the paths to the files in the project. Although you can edit many of these files directly, it is often easier and more reliable to use the visual tools.

At the top of the project hierarchy is a group file. You can combine multiple projects into a project group. This allows you to open more than one project at a time in the **Project Manager**. Project groups let you organize and work on related projects, such as applications that function together or parts of a multi-tiered application. If you are only working on one project, you do not need a project group file to create an application.

Project files, which describe individual projects, files, and associated options, have a .dpr extension. Project files contain directions for building an application or shared object. When you add and remove files using the **Project Manager**, the project file is updated. You specify project options using a Project Options dialog which has tabs for various aspects of your project such as forms, application, and compiler. These project options are stored in the project file with the project.

Units and forms are the basic building blocks of an application. A project can share any existing form and unit file including those that reside outside the project directory tree. This includes custom procedures and functions that have been written as standalone routines.

If you add a shared file to a project, realize that the file is not copied into the current project directory; it remains in its current location. Adding the shared file to the current project registers the file name and path in the **uses** clause of the project file. Delphi automatically handles this as you add units to a project.

When you compile a project, it does not matter where the files that make up the project reside. The compiler treats shared files the same as those created by the project itself.

See Also

Developing the Application User Interface: Overview (see page 1983)

3.2.4.3.3 Editing Code

The Code editor is a full-featured ASCII editor. If using the visual programming environment, a form is automatically displayed as part of a new project. You can start designing your application interface by placing objects on the form and modifying how they

work in the **Object Inspector**. But other programming tasks, such as writing event handlers for objects, must be done by typing the code.

The contents of the form, all of its properties, its components, and their properties can be viewed and edited as text in the Code editor. You can adjust the generated code in the Code editor and add more components within the editor by typing code. As you type code into the editor, the compiler is constantly scanning for changes and updating the form with the new layout. You can then go back to the form, view and test the changes you made in the editor, and continue adjusting the form from there.

The code generation and property streaming systems are completely open to inspection. The source code for everything that is included in your final executable file—all of the VCL objects, RTL sources, and project files—can be viewed and edited in the Code editor.

3.2.4.3.4 Compiling Applications

When you have finished designing your application interface on the form and writing additional code so it does what you want, you can compile the project from the IDE or from the command line.

All projects have as a target a single distributable executable file. You can view or test your application at various stages of development by compiling, building, or running it:

- When you compile, only units that have changed since the last compile are recompiled.
- When you build, all units in the project are compiled, regardless of whether they have changed since the last compile. This technique is useful when you are unsure of exactly which files have or have not been changed, or when you simply want to ensure that all files are current and synchronized. It's also important to build when you"ve changed global compiler directives to ensure that all code compiles in the proper state. You can also test the validity of your source code without attempting to compile the project.
- When you run, you compile and then execute your application. If you modified the source code since the last compilation, the compiler recompiles the changed files and any files that depend on them.

If you have grouped several projects together, you can compile or build all projects in a single project group at once. Choose **Project** ▸ **Compile All Projects**, or **Project** ▸ **Build All Projects** with the project group selected in the **Project Manager**.

3.2.4.3.5 Debugging Applications

With the integrated debugger, you can find and fix errors in your applications. The integrated debugger lets you control program execution, monitor variable values and items in data structures, and modify data values while debugging.

The integrated debugger can track down both runtime errors and logic errors. By running to specific program locations and viewing the variable values, the functions on the call stack, and the program output, you can monitor how your program behaves and find the areas where it is not behaving as designed.

You can also use exception handling to recognize, locate, and deal with errors. Exceptions are classes, like other classes in Delphi, except, by convention, they begin with an initial E rather than a T.

3.2.4.3.6 Deploying Applications

Delphi includes add-on tools to help with application deployment. For example, InstallAware Express (not available in all editions) helps you to create an installation package for your application that includes all of the files needed for running a distributed application. TeamSource software (not available in all editions) is also available for tracking application updates.

Note: Not all editions have deployment capabilities.

Refer to Deploying Applications (see page 1947) for specific information on deployment.

3.2.4.4 Deploying applications

Topics

Name	Description
Deploying BDE Applications (see page 1941)	**Warning:** The Borland Database Engine (BDE) has been deprecated, so BDE will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress. The Borland Database Engine (BDE) defines a large API for interacting with databases. Of all the data access mechanisms, the BDE supports the broadest range of functions and comes with the most supporting utilities. It is the best way to work with data in Paradox or dBASE tables. Database access for an application is provided by various... more (see page 1941)
Deploying dbExpress Database Applications (see page 1942)	dbExpress is a set of thin, native drivers that provide fast access to database information.
Deploying On Apache Servers (see page 1943)	WebBroker supports Apache version 1.3.9 and later for DLLs and CGI applications. Modules and applications are enabled and configured by modifying Apache's httpd.conf file (normally located in your Apache installation's \conf directory).
Accommodating Varying Color Depths (see page 1945)	To account for all deployment computers not being configured with the same color availability, the safest way is to use graphics with the least possible number of colors. This is especially true for control glyphs, which should typically use 16-color graphics. For displaying pictures, either provide multiple copies of the images in different resolutions and color depths or explain in the application the minimum resolution and color requirements for the application.
Deploying ActiveX Controls (see page 1945)	ActiveX controls that you create need to be registered on the deployment computer before use. Installation programs such as InstallAware Express automate this registration process. To manually register an ActiveX control, choose **Run ▶ ActiveX Server** in the IDE, use the TRegSvr demo application in \Bin or use the Microsoft utility REGSRV32.EXE (not included with Windows 9x versions). DLLs that support an ActiveX control also need to be distributed with an application.
Application Files, Listed by File Name Extension (see page 1945)	The following types of files may need to be distributed with an application. ***Application files***
Borland Database Engine (see page 1946)	**Warning:** The Borland Database Engine (BDE) has been deprecated, so BDE will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress. You can use the Borland Database Engine (BDE) to provide database access for standard Delphi data components. See the BDEDEPLOY document for specific rights and limitations on redistributing the BDE (see C:\Program Files\Common Files\Borland Shared\BDE). You should use InstallAware Express (or other certified installation program) for installing the BDE. InstallAware Express creates the necessary registry... more (see page 1946)
Considerations When Dynamically Resizing Forms and Controls (see page 1946)	If the forms and visual controls for an application are dynamically resized, accommodate all aspects of the resizing process to ensure optimal appearance of the application under all possible screen resolutions. Here are some factors to consider when dynamically resizing the visual elements of an application: • The resizing of forms and visual controls is done at a ratio calculated by comparing the screen resolution of the development computer to that of the computer onto which the application installed. Use a constant to represent one dimension of the screen resolution on the development computer: either the height or the width, in... more (see page 1946)

Considerations When Not Dynamically Resizing (see page 1947)	If the forms and visual controls that make up an application are not dynamically resized at runtime, design the application's elements for the lowest resolution. Otherwise, the forms of an application run on a computer configured for a lower screen resolution than the development computer may overlap the boundaries of the screen. For example, if the development computer is set up for a screen resolution of 1024x768 and a form is designed with a width of 700 pixels, not all of that form will be visible within the desktop on a computer configured for a 640x480 screen resolution.
DLL Locations (see page 1947)	You can install DLL files used only by a single application in the same directory as the application. DLLs that will be used by a number of applications should be installed in a location accessible to all of those applications. A common convention for locating such community DLLs is to place them either in the Windows or the Windows\System directory. A better way is to create a dedicated directory for the common .DLL files, similar to the way the Borland Database Engine is installed.
Deploying Applications: Overview (see page 1947)	Once your application is up and running, you can deploy it. That is, you can make it available for others to run. A number of steps must be taken to deploy an application to another computer so that the application is completely functional. The steps required by a given application vary, depending on the type of application. The following sections describe these steps when deploying the following applications: • Deploying General Applications (see page 1949) • Deploying Database Applications (see page 1948) • Deploying Web Applications (see page 1949) • Programming for Varying Host Environments (see page 1953) • Software License Requirements (see page 1954)
Deploying Database Applications (see page 1948)	Applications that access databases involve special installation considerations beyond copying the application's executable file onto the host computer. Database access is most often handled by a separate database engine, the files of which cannot be linked into the application's executable file. The data files, when not created beforehand, must be made available to the application. Multi-tier database applications require additional handling on installation, because the files that make up the application are typically located on multiple computers. Since several different database technologies (ADO, BDE, dbExpress, and InterBase Express) are supported, deployment requirements differ for each. Regardless of which you are... more (see page 1948)
Deploying General Applications (see page 1949)	Beyond the executable file, an application may require a number of supporting files, such as DLLs, package files, and helper applications. In addition, the Windows registry may need to contain entries for an application, from specifying the location of supporting files to simple program settings. The process of copying an application's files to a computer and making any needed registry settings can be automated by an installation program, such as InstallShield Express. Nearly all types of applications include the following issues: • Using installation programs (see page 1954) • Identifying application files (see page 1950) • Helper applications (see page 1950) • DLL locations (see page 1947) Database and Web applications require additional installation steps. For... more (see page 1949)

Deploying Web Applications (see page 1949)	Some Delphi applications are designed to be run over the World Wide Web, such as those in the form of Server-side Extension DLLs (ISAPI and Apache), CGI applications, and ActiveForms. The steps for deploying Web applications are the same as those for general applications (see page 1949), except the application's files are deployed on the Web server. Here are some special considerations for deploying Web applications: • For BDE database applications, the Borland Database Engine (or alternate database engine) is installed with the application files on the Web server. • For dbExpress applications, the dbExpress DLLs must be included in the path. If... more (see page 1949)
Fonts (see page 1950)	Windows comes with a standard set of TrueType and raster fonts. Linux comes with a standard set of fonts, depending on the distribution. When designing an application to be deployed on other computers, realize that not all computers have fonts outside the standard sets. Text components used in the application should all use fonts that are likely to be available on all deployment computers. When use of a nonstandard font is absolutely necessary in an application, you need to distribute that font with the application. Either the installation program or the application itself must install the font on the deployment... more (see page 1950)
Helper Applications (see page 1950)	Helper applications are separate programs without which your application would be partially or completely unable to function. Helper applications may be those supplied with the operating system, by CodeGear, or by third-party products. An example of a helper application is the InterBase utility program Server Manager, which administers InterBase databases, users, and security. If an application depends on a helper program, be sure to deploy it with your application, where possible. Distribution of helper programs may be governed by redistribution license agreements. Consult the helper program documentation for specific information.
Identifying Application Files (see page 1950)	Besides the executable file, a number of other files may need to be distributed with an application. • Application files (see page 1945) • Package files (see page 1952) • Merge modules (see page 1951) • ActiveX controls (see page 1945)
Merge Modules (see page 1951)	InstallAware Express is based on Windows Installer (MSI) technology. With MSI-based setup tools such as InstallAware Express, you can use merge modules for deploying runtime packages. Merge modules provide a standard method that you can use to deliver shared code, files, resources, Registry entries, and setup logic to applications as a single compound file. The runtime libraries have some interdependencies because of the way they are grouped together. The result of this is that when one package is added to an install project, the install tool automatically adds or reports a dependency on one or more other packages. For... more (see page 1951)
Deploying Multi-tiered Database Applications (DataSnap) (see page 1952)	DataSnap provides multi-tier database capability to Delphi applications by allowing client applications to connect to providers in an application server. Install DataSnap along with a multi-tier application using InstallAware (or other CodeGear-certified installation scripting utility). See the DEPLOY document (found in the main Delphi directory) for details on the files that need to be redistributed with an application. Also see the REMOTE document for related information on what DataSnap files can be redistributed and how.
Package Files (see page 1952)	If the application uses runtime packages, those package files need to be distributed with the application. InstallShield Express handles the installation of package files the same as DLLs, copying the files and making necessary entries in the Windows registry. You can also use merge modules for deploying runtime packages with MSI-based setup tools including InstallShield Express. See Merge modules (see page 1951) for details. CodeGear recommends installing the runtime package files supplied by CodeGear in the Windows\System directory. This serves as a common location so that multiple applications would have access to a single instance of the files. For packages you... more (see page 1952)

Programming for Varying Host Environments (see page 1953)	Due to the nature of various operating system environments, there are a number of factors that vary with user preference or configuration. The following factors can affect an application deployed to another computer: • Screen resolutions and color depths (see page 1953) • Fonts (see page 1950) • Operating system versions (see page 1955) • Helper applications (see page 1950) • DLL locations (see page 1947)
Screen Resolutions and Color Depths (see page 1953)	The size of the desktop and number of available colors on a computer is configurable and dependent on the hardware installed. These attributes are also likely to differ on the deployment computer compared to those on the development computer. An application's appearance (window, object, and font sizes) on computers configured for different screen resolutions can be handled in various ways: • Design the application for the lowest resolution users will have (typically, 640x480). Take no special actions to dynamically resize objects to make them proportional to the host computer's screen display. Visually, objects will appear smaller the higher the resolution is... more (see page 1953)
Software License Requirements (see page 1954)	The distribution of some files associated with Delphi applications is subject to limitations or cannot be redistributed at all. The following documents describe the legal stipulations regarding the distribution of these files:
Using Installation Programs (see page 1954)	Simple applications that consist of only an executable file are easy to install on a target computer. Just copy the executable file onto the computer. However, more complex applications that comprise multiple files require more extensive installation procedures. These applications require dedicated installation programs. Setup toolkits automate the process of creating installation programs, often without needing to write any code. Installation programs created with Setup toolkits perform various tasks inherent to installing Delphi applications, including: copying the executable and supporting files to the host computer, making Windows registry entries, and installing the Borland Database Engine for BDE database applications.... more (see page 1954)
Operating System Versions (see page 1955)	When using operating system APIs or accessing areas of the operating system from an application, there is the possibility that the function, operation, or area may not be available on computers with different operating system versions. To account for this possibility, you have a few options: • Specify in the application's system requirements the versions of the operating system on which the application can run. It is the user's responsibility to install and use the application only under compatible operating system versions. • Check the version of the operating system as the application is installed. If an incompatible version of the operating... more (see page 1955)

3.2.4.4.1 Deploying BDE Applications

Warning: The Borland Database Engine (BDE) has been deprecated, so BDE will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

The Borland Database Engine (BDE) defines a large API for interacting with databases. Of all the data access mechanisms, the BDE supports the broadest range of functions and comes with the most supporting utilities. It is the best way to work with data in Paradox or dBASE tables.

Database access for an application is provided by various database engines. An application can use the BDE or a third-party database engine. Borland Database Engine (see page 1946) describes installation of the database access elements of an application.

Deploying dbExpress Database Applications (see page 1942)

3.2.4.4.2 Deploying dbExpress Database Applications

dbExpress is a set of thin, native drivers that provide fast access to database information.

Driver packages

You can deploy a dbExpress application either as a standalone executable file or as an executable file that deploys associated dbExpress driver packages. However, you always need to deploy the database DLL for whatever databases you are using.

There are separate driver packages for each driver, which eliminates the need for a dbxdrivers.ini file. The TDBXDriver implementations have default settings for both driver and connection properties. These settings can be overridden by connection property settings. This allows many connection property settings to be minimized to a small number of property settings, such as database, user, and password.

Driver packages also contain driver specific metadata implementations. The DbxReadOnlyMetaData and DbxMetaData packages that contained metadata implementations for all drivers are no longer needed and have been removed from the product. Instead, these metadata implementations are included in their respective driver package. This makes deployment of dbExpress applications more compact, since only driver specific metadata needs to be deployed. Previously, metadata for all databases was included in the deployment, even when the application was built to run against only one database. If runtime packages are used, the number needed for deployment has been reduced by 2.

SqlExpr.pas no longer has **DbxDefaultDrivers** in its **uses** clause. If driver units are not added to an applications form or data module, the application cannot load the driver. The new driver specific units that must be added to a uses clause of your application are: dbxmysql, dbxInterbase, dbxdb2, dbxinformix, dbxmssql, dbxoracle, dbxsybase, and dbxclient (if using Blackfish SQL). This is only needed for statically linked applications.

This table below lists the database packages needed for deployment for non-standalone executables.

Note: All applications need the DbxCommonDriver120.bpl package if not built standalone.

dbExpress deployment with driver packages

Database package	When to Deploy
DbxCommonDriver120.bpl	All applications connecting to databases
DBXClientDriver120.bpl	Applications connecting to Blackfish SQL databases
DBXInformixDriver120.bpl	Applications connecting to Informix databases
DBXInterBaseDriver120.bpl	Applications connecting to InterBase databases
DBXOracleDriver120.bpl	Applications connecting to Oracle databases

DBXDb2Driver120.bpl	Applications connecting to DB2 databases
DBXSybaseASADriver120.bpl	Applications connecting to Adaptive Sybase Anywhere databases
DBXSybaseASEDriver120.bpl	Applications connecting to Sybase databases
DBXMSSQLDriver120.bpl	Applications connecting to MSSQL databases
DBXMySQLDriver120.bpl	Applications connecting to MySQL 5.0.27 databases

DbxClient drivers, currently used by Blackfish SQL, require DbxClientDriver.bpl to be deployed if packages are used. Otherwise the entire driver can be linked into an executable file, and no additional package or DLL needs to be deployed.

Driver DLLs

For database applications using Dynalink drivers, you cannot deploy a standalone executable. Instead, you can deploy associated dbExpress drivers and DLLs with your executable. If you are using DataSnap, you need to include the DataSnap DLL. The following table lists the appropriate DLLs and when to include them:

dbExpress deployment with driver DLLs

Database DLL	When to Deploy
No DLL needed	Applications connecting to Blackfish SQL databases
dbxinf.dll	Applications connecting to Informix databases
dbxint.dll	Applications connecting to InterBase databases
dbxora.dll	Applications connecting to Oracle databases
dbxdb2.dll	Applications connecting to DB2 databases
dbxasa.dll	Applications connecting to Adaptive Sybase Anywhere databases
dbxase.dll	Applications connecting to Sybase databases
dbxmss.dll	Applications connecting to MSSQL databases
dbxmys.dll	Applications connecting to MySQL 5.0.27 databases
Midas.dll	Required by database applications that use client datasets

See Using Unidirectional Datasets (see page 1823) for more information about using the dbExpress components.

3.2.4.4.3 Deploying On Apache Servers

WebBroker supports Apache version 1.3.9 and later for DLLs and CGI applications.

Modules and applications are enabled and configured by modifying Apache's httpd.conf file (normally located in your Apache installation's \conf directory).

Enabling modules

Your DLLs should be physically located in the Apache Modules subdirectory.

Two modifications to httpd.conf are required to enable a module.

The first modification is to add a LoadModule entry to let Apache locate and load your DLL. For example:

```
LoadModule MyApache_module modules/Project1.dll
```

Replace MyApache_module with the exported module name from your DLL. To find the module name, in your project source, look for the exports line. For example:

```
exports
  apache_module name 'MyApache_module';
```

The second modification is to add a resource locator entry (may be added anywhere in httpd.conf after the LoadModule entry). For example:

```
# Sample location specification for a project named project1.
<Location /project1>
SetHandler project1-handler
</Location>
```

This allows all requests to http://www.somedomain.com/project1 to be passed on to the Apache module.

The SetHandler directive specifies the Web server application that handles the request. The SetHandler argument should be set to the value of the ContentType global variable.

CGI applications

When creating CGI applications, the physical directory (specified in the Directory directive of the httpd.conf file) must have the ExecCGI option and the SetHandler clause set to allow execution of programs so the CGI script can be executed. To ensure that permissions are set up properly, use the Alias directive with both Options ExecCGI and SetHandler enabled.

Note: An alternative approach is to use the ScriptAlias directive (without Options ExecCGI), but using this approach can prevent your CGI application from reading any files in the ScriptAlias directory.

The following httpd.conf line is an example of using the Alias directive to create a virtual directory on your server and mark the exact location of your CGI script:

```
Alias/MyWeb/"c:/httpd/docs/MyWeb/"
```

This would allow requests such as /MyWeb/mycgi.exe to be satisfied by running the script c:\httpd\docs\MyWeb\mycgi.exe.

You can also set Options to All or to ExecCGI using the Directory directive in httpd.conf. The Options directive controls which server features are available in a particular directory.

Directory directives are used to enclose a set of directives that apply to the named directory and its subdirectories. An example of the Directory directive is shown below:

```
<Directory "c:/httpd/docs/MyWeb">
AllowOverride None
Options ExecCGI
Order allow,deny
Allow from all
AddHandler cgi-script exe cgi
</Directory>
```

In this example, Options is set to ExecCGI permitting execution of CGI scripts in the directory MyWeb. The AddHandler clause lets Apache know that files with extensions such as exe and cgi are CGI scripts (executables).

Note: Apache executes locally on the server within the account specified in the User directive in the httpd.conf file. Make sure that the user has the appropriate rights to access the resources needed by the application.

See the Apache LICENSE file, included with your Apache distribution, for additional deployment information. For additional Apache configuration information, see http://www.apache.org.

Creating Internet Server Applications (see page 2251)

3.2.4.4.4 Accommodating Varying Color Depths

To account for all deployment computers not being configured with the same color availability, the safest way is to use graphics with the least possible number of colors. This is especially true for control glyphs, which should typically use 16-color graphics. For displaying pictures, either provide multiple copies of the images in different resolutions and color depths or explain in the application the minimum resolution and color requirements for the application.

Considerations When Not Dynamically Resizing (see page 1947)

Considerations When Dynamically Resizing Forms and Controls (see page 1946)

3.2.4.4.5 Deploying ActiveX Controls

ActiveX controls that you create need to be registered on the deployment computer before use. Installation programs such as InstallAware Express automate this registration process. To manually register an ActiveX control, choose **Run ▸ ActiveX Server** in the IDE, use the TRegSvr demo application in \Bin or use the Microsoft utility REGSRV32.EXE (not included with Windows 9x versions).

DLLs that support an ActiveX control also need to be distributed with an application.

Application Files (see page 1945)

Using Installation Programs (see page 1954)

3.2.4.4.6 Application Files, Listed by File Name Extension

The following types of files may need to be distributed with an application.

Application files

Type	File Name Extension
Program files	.exe and .dll
Package files	.bpl and .dcp
Help files	.hlp, .cnt, and .toc (if used) or any other Help files your application supports
ActiveX files	.ocx (sometimes supported by a DLL)
Local table files	.dbf, .mdx, .dbt, .ndx, .db, .px, .y*, .x*, .mb, .val, .qbe, .gd*

See Also

Package Files (see page 1952)

ActiveX Controls (see page 1945)

3.2.4.4.7 Borland Database Engine

Warning: The Borland Database Engine (BDE) has been deprecated, so BDE will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

You can use the Borland Database Engine (BDE) to provide database access for standard Delphi data components. See the BDEDEPLOY document for specific rights and limitations on redistributing the BDE (see C:\Program Files\Common Files\Borland Shared\BDE).

You should use InstallAware Express (or other certified installation program) for installing the BDE. InstallAware Express creates the necessary registry entries and defines any aliases the application may require. Using a certified installation program to deploy the BDE files and subsets is important because:

- Improper installation of the BDE or BDE subsets can cause other applications using the BDE to fail. Such applications include not only CodeGear products, but many third-party programs that use the BDE.
- Under 32-bit Windows 95/NT and later, BDE configuration information is stored in the Windows registry instead of .ini files, as was the case under 16-bit Windows. Making the correct entries and deletions for install and uninstall is a complex task.

It is possible to install only as much of the BDE as an application actually needs. For instance, if an application only uses Paradox tables, it is only necessary to install that portion of the BDE required to access Paradox tables. This reduces the disk space needed for an application. Certified installation programs, like InstallAware Express, are capable of performing partial BDE installations. Be sure to leave BDE system files that are not used by the deployed application, but that are needed by other programs.

dbExpress Components (see page 16)

3.2.4.4.8 Considerations When Dynamically Resizing Forms and Controls

If the forms and visual controls for an application are dynamically resized, accommodate all aspects of the resizing process to ensure optimal appearance of the application under all possible screen resolutions. Here are some factors to consider when dynamically resizing the visual elements of an application:

- The resizing of forms and visual controls is done at a ratio calculated by comparing the screen resolution of the development computer to that of the computer onto which the application installed. Use a constant to represent one dimension of the screen resolution on the development computer: either the height or the width, in pixels. Retrieve the same dimension for the user's computer at runtime using the *TScreen.*Height or *TScreen*.Width property. Divide the value for the development computer by the value for the user's computer to derive the difference ratio between the two computers' screen resolutions.
- Resize the visual elements of the application (forms and controls) by reducing or increasing the size of the elements and their positions on forms. This resizing is proportional to the difference between the screen resolutions on the development and user computers. Resize and reposition visual controls on forms automatically by setting the *CustomForm*.*Scaled* form's Scaled property to *True* and calling *TWinControl.ScaleBy* its ScaleBy method . The *ScaleBy* method does not change the form's height and width, though. Do this manually by multiplying the current values for the *Height* and *Width* properties by the screen resolution difference ratio.
- The controls on a form can be resized manually, instead of automatically with the *TWinControl*.*ScaleBy* method , by referencing each visual control in a loop and setting its dimensions and position. The *Height* and *Width* property values for visual controls are multiplied by the screen resolution difference ratio. Reposition visual controls proportional to screen resolution differences by multiplying the *Top* and *Left* property values by the same ratio.
- If an application is designed on a computer configured for a higher screen resolution than that on the user's computer, font

sizes will be reduced in the process of proportionally resizing visual controls. If the size of the font at design time is too small, the font as resized at runtime may be unreadable. For example, the default font size for a form is 8. If the development computer has a screen resolution of 1024x768 and the user's computer 640x480, visual control dimensions will be reduced by a factor of 0.625 (640 / 1024 = 0.625). The original font size of 8 is reduced to 5 (8 * 0.625 = 5). Text in the application appears jagged and unreadable as it is displayed in the reduced font size.

- Some visual controls, such as *TLabel* and *TEdit*, dynamically resize when the size of the font for the control changes. This can affect deployed applications when forms and controls are dynamically resized. The resizing of the control due to font size changes are in addition to size changes due to proportional resizing for screen resolutions. This effect is offset by setting the AutoSize property of these controls to *False*.
- Avoid making use of explicit pixel coordinates, such as when drawing directly to a canvas. Instead, modify the coordinates by a ratio proportionate to the screen resolution difference ratio between the development and user computers. For example, if the application draws a rectangle to a canvas ten pixels high by twenty wide, instead multiply the ten and twenty by the screen resolution difference ratio. This ensures that the rectangle visually appears the same size under different screen resolutions.

Considerations When Not Dynamically Resizing (see page 1947)

Accommodating Varying Color Depths (see page 1945)

3.2.4.4.9 Considerations When Not Dynamically Resizing

If the forms and visual controls that make up an application are not dynamically resized at runtime, design the application's elements for the lowest resolution. Otherwise, the forms of an application run on a computer configured for a lower screen resolution than the development computer may overlap the boundaries of the screen.

For example, if the development computer is set up for a screen resolution of 1024x768 and a form is designed with a width of 700 pixels, not all of that form will be visible within the desktop on a computer configured for a 640x480 screen resolution.

See Also

Considerations When Dynamically Resizing Forms and Controls (see page 1946)

Accommodating Varying Color Depths (see page 1945)

3.2.4.4.10 DLL Locations

You can install DLL files used only by a single application in the same directory as the application. DLLs that will be used by a number of applications should be installed in a location accessible to all of those applications. A common convention for locating such community DLLs is to place them either in the Windows or the Windows\System directory. A better way is to create a dedicated directory for the common .DLL files, similar to the way the Borland Database Engine is installed.

Using Installation Programs (see page 1954)

Identifying Application Files (see page 1950)

Helper Applications (see page 1950)

3.2.4.4.11 Deploying Applications: Overview

Once your application is up and running, you can deploy it. That is, you can make it available for others to run. A number of steps must be taken to deploy an application to another computer so that the application is completely functional. The steps required by a given application vary, depending on the type of application. The following sections describe these steps when deploying the following applications:

- Deploying General Applications (see page 1949)

- Deploying Database Applications (see page 1948)
- Deploying Web Applications (see page 1949)
- Programming for Varying Host Environments (see page 1953)
- Software License Requirements (see page 1954)

See Also

Overview of Component Creation (see page 1313)

Working with Packages and Components: Overview (see page 2211)

Creating Internet Server Applications (see page 2251)

3.2.4.4.12 Deploying Database Applications

Applications that access databases involve special installation considerations beyond copying the application's executable file onto the host computer. Database access is most often handled by a separate database engine, the files of which cannot be linked into the application's executable file. The data files, when not created beforehand, must be made available to the application. Multi-tier database applications require additional handling on installation, because the files that make up the application are typically located on multiple computers.

Since several different database technologies (ADO, BDE, dbExpress, and InterBase Express) are supported, deployment requirements differ for each. Regardless of which you are using, you need to make sure that the client-side software is installed on the system where you plan to run the database application. ADO, BDE, dbExpress, and InterBase Express also require drivers to interact with the client-side software of the database.

Specific information on how to deploy dbExpress, BDE, and multi-tiered database applications is described in the following topics:

- Deploying dbExpress Database Applications (see page 1942).
- Deploying BDE Applications (see page 1941).
- Deploying Multi-tiered Database Applications (DataSnap) (see page 1952).

Database applications that use client datasets such as *TClientDataSet* or dataset providers require you to include midaslib.dcu (for static linking when providing a stand-alone executable); if you are packaging your application (with the executable and any needed DLLs), you need to include Midas.dll.

If deploying database applications that use ADO, you need to be sure that MDAC version 2.1 or later is installed on the system where you plan to run the application. MDAC is automatically installed with software such as Windows 2000 and Internet Explorer version 5 or later. You also need to be sure the drivers for the database server you want to connect to are installed on the client. No other deployment steps are required.

If deploying database applications that use InterBase Express, you need to be sure that the InterBase client is installed on the system where you plan to run the application. InterBase requires gds32.dll and interbase.msg to be located in an accessible directory. No other deployment steps are required. InterBase Express components communicate directly with the InterBase Client API and do not require additional drivers. For more information, refer to the Embedded Installation Guide posted on the CodeGear Web site.

In addition to the technologies described here, you can also use third-party database engines to provide database access. Consult the documentation or vendor for the database engine regarding redistribution rights, installation, and configuration.

3.2.4.4.13 Deploying General Applications

Beyond the executable file, an application may require a number of supporting files, such as DLLs, package files, and helper applications. In addition, the Windows registry may need to contain entries for an application, from specifying the location of supporting files to simple program settings. The process of copying an application's files to a computer and making any needed registry settings can be automated by an installation program, such as InstallShield Express. Nearly all types of applications include the following issues:

- Using installation programs (see page 1954)
- Identifying application files (see page 1950)
- Helper applications (see page 1950)
- DLL locations (see page 1947)

Database and Web applications require additional installation steps. For additional information on installing database applications, see Deploying database applications (see page 1948). For more information on installing Web applications, see Deploying Web applications (see page 1949).

See Also

Programming for Varying Host Environments (see page 1953)

Software License Requirements (see page 1954)

Deploying Packages (see page 2215)

3.2.4.4.14 Deploying Web Applications

Some Delphi applications are designed to be run over the World Wide Web, such as those in the form of Server-side Extension DLLs (ISAPI and Apache), CGI applications, and ActiveForms.

The steps for deploying Web applications are the same as those for general applications (see page 1949), except the application's files are deployed on the Web server.

Here are some special considerations for deploying Web applications:

- For BDE database applications, the Borland Database Engine (or alternate database engine) is installed with the application files on the Web server.
- For dbExpress applications, the dbExpress DLLs must be included in the path. If included, the *dbExpress* driver is installed with the application files on the Web server.
- Security for the directories should be set so that the application can access all needed database files.
- The directory containing an application must have read and execute attributes.
- The application should not use hard-coded paths for accessing database or other files.
- The location of an ActiveX control is indicated by the CODEBASE parameter of the <OBJECT> HTML tag.

For information on deploying database Web applications, see Deploying database applications (see page 1948).

For information on deploying applications on Apache servers, see Deploying on Apache servers (see page 1943).

Creating Internet Server Applications (see page 2251)

3.2.4.4.15 Fonts

Windows comes with a standard set of TrueType and raster fonts. Linux comes with a standard set of fonts, depending on the distribution. When designing an application to be deployed on other computers, realize that not all computers have fonts outside the standard sets.

Text components used in the application should all use fonts that are likely to be available on all deployment computers.

When use of a nonstandard font is absolutely necessary in an application, you need to distribute that font with the application. Either the installation program or the application itself must install the font on the deployment computer. Distribution of third-party fonts may be subject to limitations imposed by the font creator.

Windows has a safety measure to account for attempts to use a font that does not exist on the computer. It substitutes another, existing font that it considers the closest match. While this may circumvent errors concerning missing fonts, the end result may be a degradation of the visual appearance of the application. It is better to prepare for this eventuality at design time.

To make a nonstandard font available to a Windows application, use the Windows API functions *AddFontResource* and *DeleteFontResource*. Deploy the .fot file for the nonstandard font with the application.

Screen Resolutions and Color Depths (see page 1953)

Operating System Versions (see page 1955)

3.2.4.4.16 Helper Applications

Helper applications are separate programs without which your application would be partially or completely unable to function. Helper applications may be those supplied with the operating system, by CodeGear, or by third-party products. An example of a helper application is the InterBase utility program Server Manager, which administers InterBase databases, users, and security.

If an application depends on a helper program, be sure to deploy it with your application, where possible. Distribution of helper programs may be governed by redistribution license agreements. Consult the helper program documentation for specific information.

Using Installation Programs (see page 1954)

Identifying Application Files (see page 1950)

DLL Locations (see page 1947)

3.2.4.4.17 Identifying Application Files

Besides the executable file, a number of other files may need to be distributed with an application.

- Application files (see page 1945)
- Package files (see page 1952)
- Merge modules (see page 1951)
- ActiveX controls (see page 1945)

3.2.4.4.18 Merge Modules

InstallAware Express is based on Windows Installer (MSI) technology. With MSI-based setup tools such as InstallAware Express, you can use merge modules for deploying runtime packages. Merge modules provide a standard method that you can use to deliver shared code, files, resources, Registry entries, and setup logic to applications as a single compound file.

The runtime libraries have some interdependencies because of the way they are grouped together. The result of this is that when one package is added to an install project, the install tool automatically adds or reports a dependency on one or more other packages. For example, if you add the VCLInternet merge module to an install project, the install tool should also automatically add or report a dependency on the VCLDatabase and StandardVCL modules.

The dependencies for each merge module are listed in the table below. The various install tools may react to these dependencies differently. The InstallAware Express for Windows Installer automatically adds the required modules if it can find them. Other tools may simply report a dependency or may generate a build failure if all required modules are not included in the project.

Merge modules and their dependencies

Merge Module	BPLs Included	Dependencies
ADO	adortl<nnn>.bpl	DatabaseRTL, BaseRTL
BaseRTL	rtl<nnn>.bpl	No dependencies
BaseVCL	vcl<nnn>.bpl, vclx<nnn>.bpl	BaseRTL
BDEInternet	inetdbbde<nnn>.bpl	Internet, DatabaseRTL, BaseRTL, BDERTL
BDERTL	bdertl<nnn>.bpl	DatabaseRTL, BaseRTL
DatabaseRTL	dbrtl<nnn>.bpl	BaseRTL
DatabaseVCL	vcldb<nnn>.bpl	BaseVCL, DatabaseRTL, BaseRTL
DataSnap	dsnap<nnn>.bpl	DatabaseRTL, BaseRTL
DataSnapConnection	dsnapcon<nnn>.bpl	DataSnap, DatabaseRTL, BaseRTL
DataSnapEntera	dsnapent<nnn>.bpl	DataSnap, DatabaseRTL, BaseRTL, BaseVCL
DBCompatVCL	vcldbx<nnn>.bpl	DatabaseVCL, BaseVCL, BaseRTL, DatabaseRTL
dbExpress	dbexpress<nnn>.bpl	DatabaseRTL, BaseRTL
dbExpressClientDataSet	dbxcds<nnn>.bpl	BaseClientDataSet, DataBaseRTL, BaseRTL, DataSnap, dbExpress
DBXInternet	inetdbxpress<nnn>.bpl	Internet, DatabaseRTL, BaseRTL, dbExpress, DatabaseVCL, BaseVCL
DecisionCube	dss<nnn>.bpl	TeeChart, BaseVCL, BaseRTL, DatabaseVCL, DatabaseRTL, BDERTL
InterbaseVCL	ibxpress<nnn>.bpl	BaseClientDataSet, BaseRTL, BaseVCL, DatabaseRTL, DatabaseVCL, DataSnap, dbExpress
Internet	inet<nnn>.bpl, inetdb<nnn>.bpl	DatabaseRTL, BaseRTL
InternetDirect	indy<nnn>.bpl	BaseVCL, BaseRTL

Delphi Office2000Components	dcloffice2k<nnn>.bpl	DatabaseVCL, BaseVCL, DatabaseRTL, BaseRTL
C++ Office2000Components	bcboffice2k<nnn>.bpl	BaseVCL, BaseRTL
Delphi OfficeXPComponents	dclofficexp<nnn>.bpl	DatabaseVCL, BaseVCL, DatabaseRTL, BaseRTL
C++ OfficeXPComponents	bcbofficexp<nnn>.bpl	BaseVCL, BaseRTL
SOAPRTL	soaprtl<nnn>.bpl	BaseRTL, XMLRTL, DatabaseRTL, DataSnap, Internet
TeeChart	tee<nnn>.bpl, teedb<nnn>.bpl, teeqr<nnn>.bpl, teeui<nnn>.bpl	BaseVCL, BaseRTL
VCLActionBands	vclactnband<nnn>.bpl	BaseVCL, BaseRTL
VCLIE	vclie<nnn>.bpl	BaseVCL, BaseRTL
WebDataSnap	webdsnap<nnn>.bpl	XMLRTL, Internet, DataSnapConnection, DataSnap, DatabaseRTL, BaseRTL
WebSnap	websnap<nnn>.bpl, vcljpg<nnn>.bpl	WebDataSnap, XMLRTL, Internet, DataSnapConnection, DataSnap, DatabaseRTL, BaseRTL, BaseVCL
XMLRTL	xmlrtl<nnn>.bpl	Internet, DatabaseRTL, BaseRTL

3.2.4.4.19 Deploying Multi-tiered Database Applications (DataSnap)

DataSnap provides multi-tier database capability to Delphi applications by allowing client applications to connect to providers in an application server.

Install DataSnap along with a multi-tier application using InstallAware (or other CodeGear-certified installation scripting utility). See the DEPLOY document (found in the main Delphi directory) for details on the files that need to be redistributed with an application. Also see the REMOTE document for related information on what DataSnap files can be redistributed and how.

See Also

Creating Multi-tiered Applications: Overview (see page 1518)

Using Installation Programs (see page 1954)

3.2.4.4.20 Package Files

If the application uses runtime packages, those package files need to be distributed with the application. InstallShield Express handles the installation of package files the same as DLLs, copying the files and making necessary entries in the Windows registry. You can also use merge modules for deploying runtime packages with MSI-based setup tools including InstallShield Express. See Merge modules (see page 1951) for details.

CodeGear recommends installing the runtime package files supplied by CodeGear in the Windows\System directory. This serves as a common location so that multiple applications would have access to a single instance of the files. For packages you created, it is recommended that you install them in the same directory as the application. Only the .bpl files need to be distributed.

If you are distributing packages to other developers, supply the .bpl and .dcp files.

3.2.4.4.21 Programming for Varying Host Environments

Due to the nature of various operating system environments, there are a number of factors that vary with user preference or configuration. The following factors can affect an application deployed to another computer:

- Screen resolutions and color depths (see page 1953)
- Fonts (see page 1950)
- Operating system versions (see page 1955)
- Helper applications (see page 1950)
- DLL locations (see page 1947)

Deploying Web Applications (see page 1949)

Deploying Database Applications (see page 1948)

Software License Requirements (see page 1954)

Creating International Applications (see page 1923)

3.2.4.4.22 Screen Resolutions and Color Depths

The size of the desktop and number of available colors on a computer is configurable and dependent on the hardware installed. These attributes are also likely to differ on the deployment computer compared to those on the development computer.

An application's appearance (window, object, and font sizes) on computers configured for different screen resolutions can be handled in various ways:

- Design the application for the lowest resolution users will have (typically, 640x480). Take no special actions to dynamically resize objects to make them proportional to the host computer's screen display. Visually, objects will appear smaller the higher the resolution is set.
- Design using any screen resolution on the development computer and, at runtime, dynamically resize all forms and objects proportional to the difference between the screen resolutions for the development and deployment computers (a screen resolution difference ratio).
- Design using any screen resolution on the development computer and, at runtime, dynamically resize only the application's forms. Depending on the location of visual controls on the forms, this may require the forms be scrollable for the user to be able to access all controls on the forms.

The following topics are discussed in this section:

- Considerations When Not Dynamically Resizing (see page 1947)
- Considerations When Dynamically Resizing Forms and Controls (see page 1946)
- Accommodating Varying Color Depths (see page 1945)

Fonts (see page 1950)

Operating System Versions (see page 1955)

3.2.4.4.23 Software License Requirements

The distribution of some files associated with Delphi applications is subject to limitations or cannot be redistributed at all. The following documents describe the legal stipulations regarding the distribution of these files:

DEPLOY

The DEPLOY document covers the some of the legal aspects of distributing of various components and utilities, and other product areas that can be part of or associated with a Delphi application. The DEPLOY document is installed in the main Delphi directory. The topics covered include:

- .exe, .dll, and .bpl files
- Components and design-time packages
- Borland Database Engine (BDE)
- ActiveX controls
- Sample images

README

The README document contains last minute information about Delphi, possibly including information that could affect the redistribution rights for components, or utilities, or other product areas. The README document is installed in the main Delphi directory.

No-nonsense license agreement

The Delphi no-nonsense license agreement, a printed document, covers other legal rights and obligations concerning Delphi.

Third-party product documentation

Redistribution rights for third-party components, utilities, helper applications, database engines, and other products are governed by the vendor supplying the product. Consult the documentation for the product or the vendor for information regarding the redistribution of the product with Delphi applications prior to distribution.

Deploying Database Applications (see page 1948)

3.2.4.4.24 Using Installation Programs

Simple applications that consist of only an executable file are easy to install on a target computer. Just copy the executable file onto the computer. However, more complex applications that comprise multiple files require more extensive installation procedures. These applications require dedicated installation programs.

Setup toolkits automate the process of creating installation programs, often without needing to write any code. Installation programs created with Setup toolkits perform various tasks inherent to installing Delphi applications, including: copying the executable and supporting files to the host computer, making Windows registry entries, and installing the Borland Database Engine for BDE database applications.

InstallAware Express is a setup toolkit that is bundled with Delphi. InstallAware Express is certified for use with Delphi and the Borland Database Engine. It is based on Windows Installer (MSI) technology.

InstallAware Express is not automatically installed when Delphi is installed, so it must be manually installed if you want to use it to create installation programs. Run the installation program from the Delphi CD to install InstallAware Express. For more information on using InstallAware Express to create installation programs, see the InstallAware Express online help.

Other setup toolkits are available. However, if deploying BDE database applications, you should only use toolkits based on MSI technology and those which are certified to deploy the Borland Database Engine.

3.2.4.4.25 Operating System Versions

When using operating system APIs or accessing areas of the operating system from an application, there is the possibility that the function, operation, or area may not be available on computers with different operating system versions.

To account for this possibility, you have a few options:

- Specify in the application's system requirements the versions of the operating system on which the application can run. It is the user's responsibility to install and use the application only under compatible operating system versions.
- Check the version of the operating system as the application is installed. If an incompatible version of the operating system is present, either halt the installation process or at least warn the installer of the problem.
- Check the operating system version at runtime, just prior to executing an operation not applicable to all versions. If an incompatible version of the operating system is present, abort the process and alert the user. Alternately, provide different code to run dependent on different operating system versions.

  Note: Some operations are performed differently on Windows 95/98 than on Windows NT/2000/XP. Use the Windows API function *GetVersionEx* to determine the Windows version.

3.2.4.5 Developing the application user interface

Topics

Name	Description
Adding Forms (see page 1965)	To add a form to your project, select **File** ▶ **New** ▶ **Form**. You can see all your project's forms and their associated units listed in the **Project Manager** (**View** ▶ **Project Manager**) and you can display a list of the forms alone by choosing **View** ▶ **Forms**.

Adding Color, Patterns, or Pictures to Menus, Buttons, and Toolbars (see page 1966)	You can use the *Background* and *BackgroundLayout* properties to specify a color, pattern, or bitmap to use on a menu item or button. These properties also let you set up a banner the runs up the left or right side of a menu. You assign backgrounds and layouts to subitems from their action client objects. If you want to set the background of the items in a menu, in the form designer click on the menu item that contains the items. For example, selecting File lets you change the background of items appearing on the File menu. You can assign... more (see page 1966)
Adding Icons to Menus and Toolbars (see page 1966)	You can add icons next to menu items or replace captions on toolbars with icons. You organize bitmaps or icons using an *ImageList* component.
Adding Images to Menu Items (see page 1967)	Images can help users navigate in menus by matching glyphs and images to menu item action, similar to toolbar images. You can add single bitmaps to menu items, or you can organize images for your application into an image list and add them to a menu from the image list. If you're using several bitmaps of the same size in your application, it's useful to put them into an image list. To add a single image to a menu or menu item, set its *Bitmap* property to reference the name of the bitmap to use on the menu or menu... more (see page 1967)
Adding, Inserting, and Deleting Menu Items (see page 1968)	The following procedures describe how to perform the basic tasks involved in building your menu structure. Each procedure assumes you have the Menu Designer window open.
Adding a Cool Bar Component (see page 1968)	**Note:** The *TCoolBar* component requires version 4.70 or later of COMCTL32.DLL. The cool bar component (*TCoolBar*)—also called a *rebar*—displays windowed controls on independently movable, resizable bands. The user can position the bands by dragging the resizing grips on the left side of each band.
Adding a Speed Button to a Panel (see page 1969)	To add a speed button to a toolbar panel, place the speed button component (from the Additional category of the **Tool palette**) on the panel. The panel, rather than the form, "owns" the speed button, so moving or hiding the panel also moves or hides the speed button. The default height of the panel is 41, and the default height of speed buttons is 25. If you set the *Top* property of each button to 8, they'll be vertically centered. The default grid setting snaps the speed button to that vertical position for you.
Adding a Toolbar Using a Panel Component (see page 1969)	
Adding a Toolbar Using the Toolbar Component (see page 1970)	The toolbar component (*TToolBar*) offers button management and display features that panel components do not.
Adding a Tool Button (see page 1971)	To add a tool button to a toolbar, right-click on the toolbar and choose New Button. The toolbar "owns" the tool button, so moving or hiding the toolbar also moves or hides the button. In addition, all tool buttons on the toolbar automatically maintain the same height and width. You can drop other controls from the **Tool palette** onto the toolbar, and they will automatically maintain a uniform height. Controls will also wrap around and start a new row when they do not fit horizontally on the toolbar.
Adding Hidden Toolbars (see page 1971)	Toolbars do not have to be visible all the time. In fact, it is often convenient to have a number of toolbars available, but show them only when the user wants to use them. Often you create a form that has several toolbars, but hide some or all of them.
Allowing Toggle Buttons (see page 1971)	Sometimes you want to be able to click a button in a group that's already pressed and have it pop up, leaving no button in the group pressed. Such a button is called a toggle. Use *AllowAllUp* to create a grouped button that acts as a toggle: click it once, it's down; click it again, it pops up. To make a grouped speed button a toggle, set its *AllowAllUp* property to *True*. Setting *AllowAllUp* to *True* for any speed button in a group automatically sets the same property value for all buttons in the group. This enables the group... more (see page 1971)
Allowing Toggled Tool Buttons (see page 1972)	Use *AllowAllUp* to create a grouped tool button that acts as a toggle: click it once, it is down; click it again, it pops up. To make a grouped tool button a toggle, set its *AllowAllUp* property to *True*. As with speed buttons, setting *AllowAllUp* to *True* for any tool button in a group automatically sets the same property value for all buttons in the group.
Assigning a Menu to a Tool Button (see page 1972)	If you are using a toolbar (*TToolBar*) with tool buttons (*TToolButton*), you can associate menu with a specific button:

Assigning a Speed Button's Glyph (see page 1972)	Each speed button needs a graphic image called a *glyph* to indicate to the user what the button does. If you supply the speed button only one image, the button manipulates that image to indicate whether the button is pressed, unpressed, selected, or disabled. You can also supply separate, specific images for each state if you prefer. You normally assign glyphs to speed buttons at design time, although you can assign different glyphs at runtime.
Assigning Images to Tool Buttons (see page 1973)	Each tool button has an *ImageIndex* property that determines what image appears on it at runtime. If you supply the tool button only one image, the button manipulates that image to indicate whether the button is disabled.
Building Menus (see page 1973)	You add a menu component to your form, or forms, for every menu you want to include in your application. You can build each menu structure entirely from scratch, or you can start from one of the predesigned menu templates. For more information about menu templates, see Using menu templates (see page 2009). For more information about creating a menu using the menu designer see • Naming menus (see page 1991) • Naming the menu items (see page 1991) • Adding (see page 1968) • Creating submenus (see page 1978) • Adding images to menu items (see page 1967) • Viewing the menu (see page 2011)
Common Controls and XP Themes (see page 1974)	Microsoft has forked Windows common controls into two separate versions. Version 5 is available on all Windows versions from Windows 95 or later; it displays controls using a "3D chiseled" look. Version 6 became available with Windows XP. Under version 6, controls are rendered by a theme engine which matches the current Windows XP theme. If the user changes the theme, version 6 common controls will match the new theme automatically. You don't need to recompile the application. The VCL can now accommodate both types of common controls. CodeGear has added a number of components to the VCL to handle... more (see page 1974)
Controlling When Forms Reside in Memory (see page 1975)	By default, Delphi automatically creates the application's main form in memory by including the following code in the application's main entry point:
Creating and Managing Menus (see page 1975)	Menus provide an easy way for your users to execute logically grouped commands. The Menu Designer enables you to easily add a menu—either predesigned or custom tailored—to your form. You add a menu component to the form, open the Menu Designer, and type menu items directly into the Menu Designer window. You can add or delete menu items, or drag and drop them to rearrange them during design time. You don't even need to run your program to see the results—your design is immediately visible in the form, appearing just as it will during runtime. Your code can also... more (see page 1975)
Creating and Using Component Templates (see page 1975)	You can create templates that are made up of one or more components. After arranging components on a form, setting their properties, and writing code for them, save them as a *component template*. Later, by selecting the template from the **Tool palette**, you can place the preconfigured components on a form in a single step; all associated properties and event-handling code are added to your project at the same time. Once you place a template on a form, you can reposition the components independently, reset their properties, and create or modify event handlers for them just as if... more (see page 1975)
Creating Customizable Toolbars and Menus (see page 1976)	You can use action bands with the Action Manager to create customizable toolbars and menus. At runtime, users of your application can customize the toolbars and menus (action bands) in the application user interface using a customization dialog similar to the Action Manager editor.
Creating Dynamic Menus (see page 1977)	Dynamic menus and toolbars allow users to modify the application in various ways at run time. Some examples of dynamic usage include customizing the appearance of toolbars and menus, hiding unused items, and responding to most recently used lists (MRUs).

Creating Frames (see page 1977)	To create an empty frame, choose **File** ▶ **New** ▶ **Delphi Projects** ▶ **Delphi Files** and double-click Frame. You can then drop components (including other frames) onto your new frame. It is usually best—though not necessary—to save frames as part of a project. If you want to create a project that contains only frames and no forms, choose **File** ▶ **New** ▶ **Application**, close the new form and unit without saving them, then choose **File** ▶ **New** ▶ **Delphi Projects** ▶ **Delphi Files** ▶ **Frame** and save the project. **Note:** When you save frames, avoid using the default names *Unit1*, *Project1*, and so forth, since these... more (see page 1977)
Creating Most Recently Used Lists (see page 1977)	A most recently used list (MRU) reflects the user's most recently accessed files in a specific application. Using action bands, you can code MRU lists in your applications. When building MRUs for your applications, it is important not to hard code references to specific numerical indexes into the Action Manager's *ActionBars* property. At runtime, the user may change the order of items or even delete them from the action bands, which in turn will change the numerical ordering of the index. Instead of referring to index numbering, *TActionManager* includes methods that facilitate finding items by action or by caption. For... more (see page 1977)
Creating Submenus (see page 1978)	Many application menus contain drop-down lists that appear next to a menu item to provide additional, related commands. Such lists are indicated by an arrow to the right of the menu item. Delphi supports as many levels of such submenus as you want to build into your menu. Organizing your menu structure this way can save vertical screen space. However, for optimal design purposes you probably want to use no more than two or three menu levels in your interface design. (For pop-up menus, you might want to use only one submenu, if any.)
Creating Toolbars and Menus (see page 1978)	**Note:** This topic describes the recommended method for creating menus and toolbars in Windows applications. For cross-platform development, you need to use *TToolBar* and the menu components, such as *TMainMenu,* organizing them using action lists (*TActionList*). See Setting up action lists (see page 2003) for details. You use the Action Manager to automatically generate toolbars and main menus based on the actions contained in your application. The Action Manager manages standard actions and any custom actions that you have written. You then create UI elements based on these actions and use action bands to render the actions items as either menu... more (see page 1978)
Creating a Group of Speed Buttons (see page 1979)	A series of speed buttons often represents a set of mutually exclusive choices. In that case, you need to associate the buttons into a group, so that clicking any button in the group causes the others in the group to pop up. To associate any number of speed buttons into a group, assign the same number to each speed button's *GroupIndex* property. The easiest way to do this is to select all the buttons you want in the group, and, with the whole group selected, set *GroupIndex* to a unique value.
Creating Forms Dynamically (see page 1980)	You may not always want all your application's forms in memory at once. To reduce the amount of memory required at load time, you may want to create some forms only when you need to use them. For example, a dialog box needs to be in memory only during the time a user interacts with it.
Creating Groups of Tool Buttons (see page 1981)	To create a group of tool buttons, select the buttons you want to associate and set their *Style* property to *tbsCheck*; then set their *Grouped* property to *True*. Selecting a grouped tool button causes other buttons in the group to pop up, which is helpful to represent a set of mutually exclusive choices. Any unbroken sequence of adjacent tool buttons with *Style* set to *tbsCheck* and *Grouped* set to *True* forms a single group. To break up a group of tool buttons, separate the buttons with any of the following: • A tool button whose *Grouped* property is *False... more (see page 1981)*
Creating Modeless Forms Such as Windows (see page 1981)	You must guarantee that reference variables for modeless forms exist for as long as the form is in use. This means that these variables should have global scope. In most cases, you use the global reference variable that was created when you made the form (the variable name that matches the name property of the form). If your application requires additional instances of the form, declare separate global variables for each instance.

Demo Programs: Actions, Action Lists, Menus, and Toolbars (see page 1981)	For examples of Windows applications that use actions, action lists, menus, and toolbars, refer to <InstallDrive>\Documents and Settings\All Users\Documents\RAD Studio\6.0\Demos\DelphiWin32\VCLWin32\RichEdit (Windows XP), <InstallDrive>\Users\All Users\Documents\RAD Studio\6.0\Demos\DelphiWin32\VCLWin32\RichEdit (Windows Vista). In addition, the Application wizard (**File** ▶ **New** ▶ **Other**), MDI Application, SDI Application, and Winx Logo Applications can use the action and action list objects.
Designing Toolbars and Cool Bars (see page 1982)	A *toolbar* is a panel, usually across the top of a form (under the menu bar), that holds buttons and other controls. A *cool bar* (also called a rebar) is a kind of toolbar that displays controls on movable, resizable bands. If you have multiple panels aligned to the top of the form, they stack vertically in the order added. You can put controls of any sort on a toolbar. In addition to buttons, you may want to put use color grids, scroll bars, labels, and so on. You can add a toolbar to a form in several ways: • Place... more (see page 1982)
Determining the Order of Merged Menu Items: GroupIndex Property (see page 1982)	The *GroupIndex* property determines the order in which the merging menu items appear in the shared menu bar. Merging menu items can replace those on the main menu bar, or can be inserted. The default value for *GroupIndex* is 0. Several rules apply when specifying a value for *GroupIndex*:
Developing the Application User Interface: Overview (see page 1983)	When you open the IDE or create a new project, a blank form is displayed on the screen. You design your application's user interface (UI) by placing and arranging visual components, such as windows, menus, and dialog boxes, from the **Tool palette** onto the form. Once a visual component is on the form, you can adjust its position, size, and other design-time properties, and code its event handlers (see page 2149). The form takes care of the underlying programming details. The following topics describe some of the major interface tasks, such as working with forms, creating component templates, adding dialog boxes, and... more (see page 1983)
Displaying an Auto-created Form (see page 1983)	If you choose to create a form at startup, and do not want it displayed until sometime later during program execution, the form's event handler uses the *ShowModal* method to display the form that is already loaded in memory:
Editing Menu Items in the Object Inspector (see page 1983)	This topic has discussed how to set several properties for menu items—for example, the *Name* and *Caption* properties—by using the Menu Designer. The section has also described how to set menu item properties, such as the *ShortCut* property, directly in the **Object Inspector**, just as you would for any component selected in the form. When you edit a menu item by using the Menu Designer, its properties are still displayed in the **Object Inspector**. You can switch focus to the **Object Inspector** and continue editing the menu item properties there. Or you can select the menu item from... more (see page 1983)
What Happens When an Action Fires (see page 1984)	When an event fires, a series of events intended primarily for generic actions occurs. Then if the event doesn't handle the action, another sequence of events occurs.
Handling the Screen (see page 1985)	A global variable of type *TScreen* called *Screen* is created when you create a project. Screen encapsulates the state of the screen on which your application is running. Common tasks performed by *Screen* include specifying: • The look of the cursor. • The size of the window in which your application is running. • A list of fonts available to the screen device. • Multiple screen behavior (Windows only). If your Windows application runs on multiple monitors, *Screen* maintains a list of monitors and their dimensions so that you can effectively manage the layout of your user interface.
Hiding the Main Form (see page 1986)	You can prevent the main form from appearing when your application starts by using the global Application variable (see page 2012).

Hiding Unused Items and Categories in Action Bands (see page 1986)	One benefit of using ActionBands is that unused items and categories can be hidden from the user. Over time, the action bands become customized for the application users, showing only the items that they use and hiding the rest from view. Hidden items can become visible again when the user presses a drop-down button. Also, the user can restore the visibility of all action band items by resetting the usage statistics from the customization dialog. Item hiding is the default behavior of action bands, but that behavior can be changed to prevent hiding of individual items, all the items in... more (see page 1986)
Hiding and Showing Toolbars (see page 1987)	Often, you want an application to have multiple toolbars, but you do not want to clutter the form with them all at once. Or you may want to let users decide whether to display toolbars. As with all components, toolbars can be shown or hidden at runtime as needed. To show or hide a toolbar at runtime, set its *Visible* property to *False* or *True*, respectively. Usually you do this in response to particular user events or changes in the operating mode of the application. To do this, you typically have a close button on each toolbar. When the... more (see page 1987)
How Actions Find Their Targets (see page 1987)	What happens when an action fires (see page 1984) describes the execution cycle that occurs when a user invokes an action. If no event handler is assigned to respond to the action, either at the action list, application, or action level, then the application tries to identify a target object to which the action can apply itself. The application looks for the target using the following sequence: 1. Active control: The application looks first for an active control as a potential target. 2. Active form: If the application does not find an active control or if the active control can't act as a target, it... more (see page 1987)
Developing Dialog Boxes (see page 1988)	The dialog box components on the Dialogs category of the **Tool palette** make various dialog boxes available to your applications. These dialog boxes provide applications with a familiar, consistent interface that enables the user to perform common file operations such as opening, saving, and printing files. Dialog boxes display and/or obtain data. Each dialog box opens when its *Execute* method is called. *Execute* returns a Boolean value: if the user chooses OK to accept any changes made in the dialog box, *Execute* returns *True*; if the user chooses Cancel to escape from the dialog box without making or... more (see page 1988)
Importing Resource Files (see page 1988)	You can build menus with other applications, so long as the menus are in the standard Windows resource (.RC) file format. You can import such menus directly into your project, saving you the time and effort of rebuilding menus that you created elsewhere.
Managing Layout (see page 1988)	At its simplest, you control the layout of your user interface by where you place controls in your forms. The placement choices you make are reflected in the control's *Top*, *Left*, *Width*, and *Height* properties. You can change these values at runtime to change the position and size of the controls in your forms. Controls have a number of other properties, however, that allow them to automatically adjust to their contents or containers. This allows you to lay out your forms so that the pieces fit together into a unified whole. Two properties affect how a... more (see page 1988)
Manipulating Menu Items at Runtime (see page 1989)	Sometimes you want to add menu items to an existing menu structure while the application is running, to provide more information or options to the user. You can insert a menu item by using the menu item's *Add* or *Insert* method, or you can alternately hide and show the items in a menu by changing their *Visible* property. The *Visible* property determines whether the menu item is displayed in the menu. To dim a menu item without hiding it, use the Enabled property. For examples that use the menu item's *Visible* and *Enabled* properties, see Disabling menu items (see page 2160). In... more (see page 1989)
Merging Menus (see page 1989)	For MDI applications, such as the text editor sample application, and for OLE client applications, your application's main menu needs to be able to receive menu items either from another form or from the OLE server object. This is often called *merging menus*. Note that OLE technology is limited to Windows applications only and is not available for use in cross-platform programming. You prepare menus for merging by specifying values for two properties: • *Menu*, a property of the form • *GroupIndex*, a property of menu items in the menu

Using Forms (see page 1990)	When you create a form from the IDE, Delphi automatically creates the form in memory by including code in the main entry point of your application function. Usually, this is the desired behavior and you don't have to do anything to change it. That is, the main window persists through the duration of your program, so you would likely not change the default behavior when creating the form for your main window. However, you may not want all your application's forms in memory for the duration of the program execution. That is, if you do not want all your application's... more (see page 1990)
Moving Menu Items (see page 1990)	During design time, you can move menu items simply by dragging and dropping. You can move menu items along the menu bar, or to a different place in the menu list, or into a *different* menu entirely. The only exception to this is hierarchical: you cannot demote a menu item from the menu bar into its own menu; nor can you move a menu item into its own submenu. However, you can move any item into a different menu, no matter what its original position is. While you are dragging, the cursor changes shape to indicate whether you can release... more (see page 1990)
Naming Conventions for Template Menu Items and Event Handlers (see page 1990)	When you save a menu as a template, Delphi does not save its *Name* property, since every menu must have a unique name within the scope of its owner (the form). However, when you insert the menu as a template into a new form by using the Menu Designer, Delphi then generates new names for it and all of its items. For example, suppose you save a File menu as a template. In the original menu, you name it *MyFile*. If you insert it as a template into a new menu, Delphi names it *File1*. If you insert... more (see page 1990)
Naming Menus (see page 1991)	As with all components, when you add a menu component to the form, the form gives it a default name; for example, *MainMenu1*. You can give the menu a more meaningful name that follows language naming conventions. The menu name is added to the form's type declaration, and the menu name then appears in the Component list.
Naming the Menu Items (see page 1991)	In contrast to the menu component itself, you need to explicitly name menu items as you add them to the form. You can do this in one of two ways: • Directly type the value for the *Name* property. • Type the value for the *Caption* property first, and let Delphi derive the *Name* property from the caption. For example, if you give a menu item a *Caption* property value of File, Delphi assigns the menu item a *Name* property of *File1*. If you fill in the *Name* property before filling in the *Caption* property, Delphi leaves the *Caption* property blank... more (see page 1991)
Opening the Menu Designer (see page 1992)	You design menus for your application using the Menu Designer. Before you can start using the Menu Designer, first add either a *TMainMenu* or *TPopupMenu* component to your form. Both menu components are located on the Standard category of the **Tool palette**.  A MainMenu component creates a menu that's attached to the form's title bar. A PopupMenu component creates a menu that appears when the user right-clicks in the form. Pop-up menus do not have a menu bar. To open the Menu Designer, select a menu component on the form, and then either: • Double-click the... more (see page 1992)
Organizing Actions for Toolbars and Menus (see page 1992)	Several features simplify the work of creating, customizing, and maintaining menus and toolbars. These features allow you to organize lists of actions that users of your application can initiate by pressing a button on a toolbar, choosing a command on a menu, or pointing and clicking on an icon. Often a set of actions is used in more than one user interface element. For example, the Cut, Copy, and Paste commands often appear on both an Edit menu and on a toolbar. You only need to add the action once to use it in multiple UI elements in your application.... more (see page 1992)

Passing Additional Arguments to Forms (see page 1993)	Typically, you create forms for your application from within the IDE. When created this way, the forms have a constructor that takes one argument, *Owner*, which is the owner of the form being created. (The owner is the calling application object or form object.) *Owner* can be **nil**. To pass additional arguments to a form, create a separate constructor and instantiate the form using this new constructor. The example form class below shows an additional constructor, with the extra argument *whichButton*. This new constructor is added to the form class manually.
Predefined Action Classes (see page 1995)	You can add predefined actions to your application by right-clicking on the Action Manager and choosing New Standard Action. The New Standard Action Classes dialog box is displayed listing the predefined action classes and the associated standard actions. These are actions that are included with Delphi and they are objects that automatically perform actions. The predefined actions are organized within the following classes:
Registering Actions (see page 1996)	When you write your own actions, you can register actions to enable them to appear in the Action List editor. You register and unregister actions by using the global routines in the Actnlist unit:
Responding to Clicks (see page 1996)	When the user clicks a control, such as a button on a toolbar, the application generates an *OnClick* event which you can respond to with an event handler. Since *OnClick* is the default event for buttons, you can generate a skeleton handler for the event by double-clicking the button at design time. For general information about events and event handlers, see Working with Events and Event Handlers (see page 2149) and Generating a handler for a component's default event (see page 2147).
Retrieving Data from Forms (see page 1997)	Most real-world applications consist of several forms. Often, information needs to be passed between these forms. Information can be passed to a form by means of parameters to the receiving form's constructor, or by assigning values to the form's properties. The way you get information from a form depends on whether the form is modal or modeless.
Retrieving Data from Modal Forms (see page 1997)	Just like modeless forms, modal forms often contain information needed by other forms. The most common example is when form A launches modal form B. When form B is closed, form A needs to know what the user did with form B to decide how to proceed with the processing of form A. If form B is still in memory, it can be queried through properties or member functions just as in the modeless forms example above. But how do you handle situations where form B is deleted from memory upon closing? Since a form does not have an explicit... more (see page 1997)
Retrieving Data from Modeless Forms (see page 1999)	You can easily extract information from modeless forms by calling public member functions of the form or by querying properties of the form. For example, assume an application contains a modeless form called *ColorForm* that contains a listbox called *ColorListBox* with a list of colors ("Red," "Green," "Blue," and so on). The selected color name string in *ColorListBox* is automatically stored in a property called *CurrentColor* each time a user selects a new color. The class declaration for the form is as follows:
Reusing Components and Groups of Components (see page 2000)	You can save and reuse work you've done with components using several tools: • Configure and save groups of components in component templates (see page 1975). • Save forms, data modules, and projects in the Object Repository (see page 1917). The Repository gives you a central database of reusable elements and lets you use form inheritance to propagate changes. • Save frames (see page 2012) on the **Tool palette** or in the Repository. Frames use form inheritance and can be embedded into forms or other frames. • Create a custom component (see page 1313), the most complicated but most flexible way of reusing code. See Overview of Component Creation (see page 1313).
Saving a Menu as a Template (see page 2001)	Any menu you design can be saved as a template so you can use it again. You can use menu templates to provide a consistent look to your applications, or use them as a starting point which you then further customize. The menu templates you save are stored in your BIN subdirectory as .dmt files.

Selecting Menu and Toolbar Styles (see page 2001)	Just as you can add different colors and icons to individual menus and toolbars, you can select different menu and toolbar styles to give your application a comprehensive look and feel. In addition to the standard style, your application can take on the look of Windows XP, Encarta™, or a custom presentation using a coordinated color scheme. To give your application a coherent look and feel, the IDE uses colormaps. A colormap can be simple, merely adding the appropriate colors to existing menus and toolbars. Or, a colormap can be complex, altering numerous subtle details of a menu's or toolbar's... more (see page 2001)
Setting Up Action Bands (see page 2002)	Because actions do not maintain any "layout" (either appearance or positional) information, Delphi provides action bands which are capable of storing this data. Action bands provide a mechanism that allows you to specify layout information and a set of controls. You can render actions as UI elements such as toolbars and menus. You organize sets of actions using the Action Manager (TActionManager). You can use standard actions provided or create new actions of your own. You then create the action bands: • Use TActionMainMenuBar to create a main menu. • Use TActionToolBarto create a toolbar. The action bands act as containers... more (see page 2002)
Setting Up Action Lists (see page 2003)	Setting up action lists is fairly easy once you understand the basic steps involved: • Create the action list. • Add actions to the action list. • Set properties on the actions. • Attach clients to the action.
Setting the Appearance of the Cool Bar (see page 2003)	The cool bar component offers several useful configuration options. The table below lists some actions you can set to change a tool button's appearance: ***Setting a cool button's appearance***
Setting the Initial Condition of a Speed Button (see page 2004)	Speed buttons use their appearance to give the user clues as to their state and purpose. Because they have no caption, it's important that you use the right visual cues to assist users. The table below lists some actions you can set to change a speed button's appearance: ***Setting speed buttons' appearance***
Setting Tool Button Appearance and Initial Conditions (see page 2004)	The table below lists some actions you can set to change a tool button's appearance: ***Setting tool buttons' appearance***
Sharing Frames (see page 2005)	You can share a frame with other developers in two ways: • Add the frame to the Object Repository. • Distribute the frame's unit (.pas) and form (.dfm or .xfm) files. To add a frame to the Repository, open any project that includes the frame, right-click in the Form Designer, and choose Add to Repository. For more information, see Using the Object Repository (see page 1917). If you send a frame's unit and form files to other developers, they can open them and add them to the **Tool palette**. If the frame has other frames embedded in it, they will have to open... more (see page 2005)

Specifying Accelerator Keys and Keyboard Shortcuts (see page 2005)	Accelerator keys enable the user to access a menu command from the keyboard by pressing Alt+ the appropriate letter, indicated in your code by the preceding ampersand. The letter after the ampersand appears underlined in the menu. Delphi automatically checks for duplicate accelerators and adjusts them at runtime. This ensures that menus built dynamically at runtime contain no duplicate accelerators and that all menu items have an accelerator. You can turn off this automatic checking by setting the *AutoHotkeys* property of a menu item to *maManual*. To specify an accelerator, add an ampersand in front of the appropriate... more (see page 2005)
Specifying the Active Menu: Menu Property (see page 2006)	The *Menu* property specifies the active menu for the form. Menu-merging operations apply only to the active menu. If the form contains more than one menu component, you can change the active menu at runtime by setting the *Menu* property in code. For example,
Switching Between Menus at Design Time (see page 2006)	If you're designing several menus for your form, you can use the Menu Designer context menu or the **Object Inspector** to easily select and move among them.
Controlling Application Behavior (see page 2007)	TApplication, TScreen, and TForm are the classes that form the backbone of all applications by controlling the behavior of your project. The *TApplication* class forms the foundation of an application by providing properties and methods that encapsulate the behavior of a standard program. *TScreen* is used at runtime to keep track of forms and data modules that have been loaded as well as maintaining system-specific information such as screen resolution and available display fonts. Instances of the *TForm* class are the building blocks of your application's user interface. The windows and dialog boxes in your application are based on *TForm... more (see page 2007)*
Updating Actions (see page 2007)	When the application is idle, the *OnUpdate* event occurs for every action that is linked to a control or menu item that is showing. This provides an opportunity for applications to execute centralized code for enabling and disabling, checking and unchecking, and so on. For example, the following code illustrates the *OnUpdate* event handler for an action that is "checked" when the toolbar is visible:
Using Action Lists (see page 2007)	**Note:** The contents of this topic apply to setting up toolbars and menus for cross-platform development. For Windows development you can also use the methods described here. However, using action bands instead is simpler and offers more options. The action lists will be handled automatically by the Action Manager. See Organizing actions for toolbars and menus (see page 1992) for details. Action lists maintain a list of actions that your application can take in response to something a user does. By using action objects, you centralize the functions performed by your application from the user interface. This lets you share common code for... more (see page 2007)
Using and Modifying Frames (see page 2008)	To use a frame in an application, you must place it, directly or indirectly, on a form. You can add frames directly to forms, to other frames, or to other container objects such as panels and scroll boxes. The Form Designer provides two ways to add a frame to an application: • Select a frame from the **Tool palette** and drop it onto a form, another frame, or another container object. If necessary, the Form Designer asks for permission to include the frame's unit file in your project. • Select *Frames* from the Standard category of the **Tool palette** and click on... more (see page 2008)
Using Menu Templates (see page 2009)	Several predesigned menus, or menu templates, contain frequently used commands. You can use these menus in your applications without modifying them (except to write code), or you can use them as a starting point, customizing them as you would a menu you originally designed yourself. Menu templates do not contain any event handler code. The menu templates are stored in the BIN subdirectory in a default installation and have a .dmt extension. You can also save as a template any menu that you design using the Menu Designer. After saving a menu as a template, you can use it as... more (see page 2009)
Using the Main Form (see page 2009)	The first form you create and save in a project becomes, by default, the project's main form, which is the first form created at runtime. As you add forms to your projects, you might decide to designate a different form as your application's main form. Also, specifying a form as the main form is an easy way to test it at runtime, because unless you change the form creation order, the main form is the first form displayed in the running application.

Using the Menu Designer Context Menu (see page 2010)	The Menu Designer context menu provides quick access to the most common Menu Designer commands, and to the menu template options. (For more information about menu templates, refer to Using menu templates (see page 2009).) To display the context menu, right-click the Menu Designer window, or press *Alt+F10* when the cursor is in the Menu Designer window.
Creating a Form Instance Using a Local Variable (see page 2010)	A safer way to create a unique instance of a *modal form* is to use a local variable in the event handler as a reference to a new instance. If a local variable is used, it does not matter whether *ResultsForm* is auto-created or not. The code in the event handler makes no reference to the global form variable. For example:
Viewing the Menu (see page 2011)	You can view your menu in the form at design time without first running your program code. (Pop-up menu components are visible in the form at design time, but the pop-up menus themselves are not. Use the Menu Designer to view a pop-up menu at design time.)
What Is an Action? (see page 2011)	As you are developing your application, you can create a set of actions that you can use on various UI elements. You can organize them into categories that can be dropped onto a menu as a set (for example, Cut, Copy, and Paste) or one at a time (for example, **Tools** ▶ **Customize**). An action corresponds to one or more elements of the user interface, such as menu commands or toolbar buttons. Actions serve two functions: (1) they represent properties common to the user interface elements, such as whether a control is enabled or checked, and (2) they respond... more (see page 2011)
Working at the Application Level (see page 2012)	The global variable *Application*, of type *TApplication*, is in every VCL-based application. *Application* encapsulates your application as well as providing many functions that occur in the background of the program. For instance, *Application* handles how you call a Help file from the menu of your program. Understanding how *TApplication* works is more important to a component writer than to developers of stand-alone applications, but you should set the options that *Application* handles in the **Project** ▶ **Options** Application page when you create a project. In addition, *Application* receives many events that apply to the application as a whole. For... more (see page 2012)
Working with Frames (see page 2012)	A frame (*TFrame*), like a form, is a container for other components. It uses the same ownership mechanism as forms for automatic instantiation and destruction of the components on it, and the same parent-child relationships for synchronization of component properties. In some ways, however, a frame is more like a customized component than a form. Frames can be saved on the **Tool palette** for easy reuse, and they can be nested within forms, other frames, or other container objects. After a frame is created and saved, it continues to function as a unit and to inherit changes from... more (see page 2012)
Writing Action Components (see page 2013)	You can also create your own predefined action classes. When you write your own action classes, you can build in the ability to execute on certain target classes of objects. Then, you can use your custom actions in the same way you use predefined action classes. That is, when the action can recognize and apply itself to a target class, you can simply assign the action to a client control, and it acts on the target with no need to write an event handler. Component writers can use the classes in the QStdActns and DBActns units as examples for... more (see page 2013)
Using Windows Common Dialog Boxes (see page 2013)	One of the commonly used dialog box components is *TOpenDialog*. This component is usually invoked by a New or Open menu item under the File option on the main menu bar of a form. The dialog box contains controls that let you select groups of files using a wildcard character and navigate through directories. The *TOpenDialog* component makes an Open dialog box available to your application. The purpose of this dialog box is to let a user specify a file to open. You use the *Execute* method to display the dialog box. When the user chooses OK in the... more (see page 2013)

3.2.4.5.1 Adding Forms

To add a form to your project, select **File** ▶ **New** ▶ **Form**. You can see all your project's forms and their associated units listed in the **Project Manager** (**View** ▶ **Project Manager**) and you can display a list of the forms alone by choosing **View** ▶ **Forms**.

Linking forms

Adding a form to a project adds a reference to it in the project file, but not to any other units in the project. Before you can write code that references the new form, you need to add a reference to it in the referencing forms' unit files. This is called *form linking*.

A common reason to link forms is to provide access to the components in that form. For example, you'll often use form linking to

enable a form that contains data-aware components to connect to the data-access components in a data module.

To link a form to another form:

1. Select the form that needs to refer to another.
2. Choose **File ▸ Use Unit**.
3. Select the name of the form unit for the form to be referenced.
4. Choose OK.

Linking a form to another just means that the **uses** clauses of one form unit contains a reference to the other's form unit, meaning that the linked form and its components are now in scope for the linking form.

Avoiding circular unit references

When two forms must reference each other, it's possible to cause a "Circular reference" error when you compile your program. To avoid such an error, do one of the following:

- Place both **uses** clauses, with the unit identifiers, in the **implementation** parts of the respective unit files. (This is what the **File ▸ Use Unit** command does.)
- Place one **uses** clause in an **interface** part and the other in an **implementation** part. (You rarely need to place another form's unit identifier in this unit's **interface** part.)

Do not place both **uses** clauses in the **interface** parts of their respective unit files. This generates the "Circular reference" error at compile time.

TForm

3.2.4.5.2 Adding Color, Patterns, or Pictures to Menus, Buttons, and Toolbars

You can use the *Background* and *BackgroundLayout* properties to specify a color, pattern, or bitmap to use on a menu item or button. These properties also let you set up a banner the runs up the left or right side of a menu.

You assign backgrounds and layouts to subitems from their action client objects. If you want to set the background of the items in a menu, in the form designer click on the menu item that contains the items. For example, selecting File lets you change the background of items appearing on the File menu. You can assign a color, pattern, or bitmap in the *Background* property in the **Object Inspector**.

Use the *BackgroundLayout* property to describe how to place the background on the element. Colors or images can be placed behind the caption normally, stretched to fit the item area, or tiled in small squares to cover the area.

Items with normal (blNormal), stretched (blStretch), or tiled (blTile) backgrounds are rendered with a transparent background. If you create a banner, the full image is placed on the left (blLeftBanner) or the right (blRightBanner) of the item. You need to make sure it is the correct size because it is not stretched or shrunk to fit.

To change the background of an action band (that is, on a main menu or toolbar), select the action band and choose the *TActionClientBar* through the action band collection editor. You can set *Background* and *BackgroundLayout* properties to specify a color, pattern, or bitmap to use on the entire toolbar or menu.

See Also

Setting Up Action Lists (see page 2003)

3.2.4.5.3 Adding Icons to Menus and Toolbars

You can add icons next to menu items or replace captions on toolbars with icons. You organize bitmaps or icons using an *ImageList* component.

To add icons to menus and toolbars:

1. Drop an *ImageList* component from the Win32 category of the **Tool palette** onto a form.
2. Add the images you want to use to the image list: Double-click the *ImageList* icon. Click Add and navigate to the images you want to use and click OK when done. Some sample images are included in Program Files\Common Files\Borland Shared\Images. (The buttons images include two views of each for active and inactive buttons.)
3. From the Additional category of the **Tool palette**, drop one or more of the following action bands onto the form:

- TActionMainMenuBar(for designing main menus)
- TActionToolBar *(for designing* toolbars)

4. Connect the image list to the Action Manager. First, set the focus on the Action Manager. Next, in the **Object Inspector**, select the name of the image list from the *Images* property, such as `ImageList1`.
5. Use the Action Manager editor to add actions to the Action Manager. You can associate an image with an action by setting its *ImageIndex* property to its number in the image list.
6. Drag and drop single actions or categories of actions from the Action Manager editor onto the menu or toolbar.
7. For toolbars where you only want to display the icon and no caption: select the Toolbar action band and double-click its Items property. In the collection editor, you can select one or more items and set their *Caption* properties.
8. The images automatically appear on the menu or toolbar.

TCustomActionMainMenuBar

TActionToolBar

3.2.4.5.4 Adding Images to Menu Items

Images can help users navigate in menus by matching glyphs and images to menu item action, similar to toolbar images. You can add single bitmaps to menu items, or you can organize images for your application into an image list and add them to a menu from the image list. If you're using several bitmaps of the same size in your application, it's useful to put them into an image list.

To add a single image to a menu or menu item, set its *Bitmap* property to reference the name of the bitmap to use on the menu or menu item.

To add an image to a menu item using an image list:

1. Drop a *TMainMenu* or *TPopupMenu* object on a form.
2. Drop a *TImageList* object on the form.
3. Open the ImageList editor by double clicking on the *TImageList* object.
4. Click Add to select the bitmap or bitmap group you want to use in the menu. Click OK.
5. Set the *TMainMenu* or *TPopupMenu* object's *Images* property to the ImageList you just created.
6. Create your menu items and submenu items as described in this topic group.
7. Select the menu item you want to have an image in the **Object Inspector** and set the *ImageIndex* property to the corresponding number of the image in the *ImageList* (the default value for *ImageIndex* is -1, which doesn't display an image).

   Note: Use images that are 16 by 16 pixels for proper display in the menu. Although you can use other sizes for the menu images, alignment and consistency problems may result when using images greater than or smaller than 16 by 16 pixels.

Adding Graphics to Controls (see page 2154)

TMenu

Creating and Managing Menus (see page 1975)

3.2.4.5.5 Adding, Inserting, and Deleting Menu Items

The following procedures describe how to perform the basic tasks involved in building your menu structure. Each procedure assumes you have the Menu Designer window open.

To add menu items at design time:

1. Select the position where you want to create the menu item.
2. If you've just opened the Menu Designer, the first position on the menu bar is already selected. Begin typing to enter the caption. Or enter the *Name* property first by specifically placing your cursor in the **Object Inspector** and entering a value. In this case, you then need to reselect the *Caption* property and enter a value.
3. Press `Enter`. The next placeholder for a menu item is selected. If you entered the *Caption* property first, use the arrow keys to return to the menu item you just entered. You'll see that Delphi has filled in the *Name* property based on the value you entered for the caption. (See Naming the menu items (see page 1991).)
4. Continue entering values for the *Name* and *Caption* properties for each new item you want to create, or press `Esc` to return to the menu bar. Use the arrow keys to move from the menu bar into the menu, and to then move between items in the list; press `Enter` to complete an action. To return to the menu bar, press `Esc` .

To insert a new, blank menu item:

1. Place the cursor on a menu item.
2. Press `Ins`. Menu items are inserted to the left of the selected item on the menu bar, and above the selected item in the menu list.

To delete a menu item or command:

1. Place the cursor on the menu item you want to delete.
2. Press `Del`.

   Note: You cannot delete the default placeholder that appears below the item last entered in a menu list, or next to the last item on the menu bar. This placeholder does not appear in your menu at runtime.

   Separator bars insert a line between menu items and items on a toolbar. You can use separator bars to indicate groupings within the menu list or toolbar, or simply to provide a visual break in a list.

   To add a separator bar to a menu:

- Add a menu item as described above and type a hyphen (-) for the caption.
- Or press the hyphen (-) key while the cursor is positioned on the menu where you want a separator to appear.

To add a separator bar onto a TActionToolBar, press the insert key and set the new item's caption to a separtor bar (|) or hyphen (-).

To add accelerators or shortcuts to menu items, see Specifying accelerator keys and keyboard shortcuts (see page 2005).

3.2.4.5.6 Adding a Cool Bar Component

Note: The *TCoolBar* component requires version 4.70 or later of COMCTL32.DLL.

The cool bar component (*TCoolBar*)—also called a *rebar*—displays windowed controls on independently movable, resizable

bands. The user can position the bands by dragging the resizing grips on the left side of each band.

To add a cool bar to a form in a VCL application:

1. Add a cool bar component to the form (from the Win32 page of the **Tool palette**). The cool bar automatically aligns to the top of the form.
2. Add windowed controls from the **Tool palette** to the bar.

Only VCL components that descend from *TWinControl* are windowed controls. You can add graphic controls—such as labels or speed buttons—to a cool bar, but they will not appear on separate bands.

3.2.4.5.7 Adding a Speed Button to a Panel

To add a speed button to a toolbar panel, place the speed button component (from the Additional category of the **Tool palette**) on the panel.

The panel, rather than the form, "owns" the speed button, so moving or hiding the panel also moves or hides the speed button.

The default height of the panel is 41, and the default height of speed buttons is 25. If you set the *Top* property of each button to 8, they'll be vertically centered. The default grid setting snaps the speed button to that vertical position for you.

3.2.4.5.8 Adding a Toolbar Using a Panel Component

To add a toolbar to a form using the panel component

1. Add a panel component to the form (from the Standard category of the **Tool palette**).
2. Set the panel's *Align* property to *alTop*. When aligned to the top of the form, the panel maintains its height, but matches its width to the full width of the form's client area, even if the window changes size.
3. Add speed buttons or other controls to the panel.

Speed buttons are designed to work on toolbar panels. A speed button usually has no caption, only a small graphic (called a *glyph*), which represents the button's function.

Speed buttons have three possible modes of operation. They can

- Act like regular pushbuttons
- Toggle on and off when clicked

- Act like a set of radio buttons

To implement speed buttons on toolbars, do the following:

- Adding a speed button to a panel (see page 1969).
- Assigning a speed button's glyph (see page 1972).
- Setting the initial condition of a speed button (see page 2004).
- Creating a group of speed buttons (see page 1979).
- Allowing toggle buttons (see page 1971).

3.2.4.5.9 Adding a Toolbar Using the Toolbar Component

The toolbar component (*TToolBar*) offers button management and display features that panel components do not.

To add a toolbar to a form using the toolbar component

1. Add a toolbar component to the form (from the Win32/Common Controls category of the **Tool palette**). The toolbar automatically aligns to the top of the form.
2. Add tool buttons or other controls to the bar.

Tool buttons are designed to work on toolbar components. Like speed buttons, tool buttons can:

- Act like regular pushbuttons.
- Toggle on and off when clicked.
- Act like a set of radio buttons.

To implement tool buttons on a toolbar, do the following:

- Adding a tool button (see page 1971)
- Assigning images to tool buttons (see page 1973)
- Setting tool button appearance and initial conditions (see page 2004)
- Creating groups of tool buttons (see page 1981)
- Allowing toggled tool buttons (see page 1972)

3.2.4.5.10 Adding a Tool Button

To add a tool button to a toolbar, right-click on the toolbar and choose New Button.

The toolbar "owns" the tool button, so moving or hiding the toolbar also moves or hides the button. In addition, all tool buttons on the toolbar automatically maintain the same height and width. You can drop other controls from the **Tool palette** onto the toolbar, and they will automatically maintain a uniform height. Controls will also wrap around and start a new row when they do not fit horizontally on the toolbar.

3.2.4.5.11 Adding Hidden Toolbars

Toolbars do not have to be visible all the time. In fact, it is often convenient to have a number of toolbars available, but show them only when the user wants to use them. Often you create a form that has several toolbars, but hide some or all of them.

To create a hidden toolbar:

1. Add a toolbar, cool bar, or panel component to the form.
2. Set the component's *Visible* property to *False*.

Although the toolbar remains visible at design time so you can modify it, it remains hidden at runtime until the application specifically makes it visible.

3.2.4.5.12 Allowing Toggle Buttons

Sometimes you want to be able to click a button in a group that's already pressed and have it pop up, leaving no button in the group pressed. Such a button is called a toggle. Use *AllowAllUp* to create a grouped button that acts as a toggle: click it once, it's down; click it again, it pops up.

To make a grouped speed button a toggle, set its *AllowAllUp* property to *True*.

Setting *AllowAllUp* to *True* for any speed button in a group automatically sets the same property value for all buttons in the group. This enables the group to act as a normal group, with only one button pressed at a time, but also allows every button to be up at the same time.

See Also

3.2.4.5.14 Assigning a Menu to a Tool Button

If you are using a toolbar (*TToolBar*) with tool buttons (*TToolButton*), you can associate menu with a specific button:

To assign a menu to a tool button

1. Select the tool button.
2. In the **Object Inspector**, assign a pop-up menu (*TPopupMenu*) to the tool button's *DropDownMenu* property.

If the menu's *AutoPopup* property is set to *True*, it will appear automatically when the button is pressed.

See Also

TToolBar

TCoolBar

TPanel

TToolButton

TSpeedButton

3.2.4.5.15 Assigning a Speed Button's Glyph

Each speed button needs a graphic image called a *glyph* to indicate to the user what the button does. If you supply the speed button only one image, the button manipulates that image to indicate whether the button is pressed, unpressed, selected, or disabled. You can also supply separate, specific images for each state if you prefer.

You normally assign glyphs to speed buttons at design time, although you can assign different glyphs at runtime.

To assign a glyph to a speed button at design time

1. Select the speed button.
2. In the Object Inspector, select the *Glyph* property.
3. Double-click the Value column beside *Glyph* to open the Picture Editor and select the desired bitmap.

See Also

TToolBar

TCoolBar

TPanel

TToolButton

TSpeedButton

3.2.4.5.16 Assigning Images to Tool Buttons

Each tool button has an *ImageIndex* property that determines what image appears on it at runtime. If you supply the tool button only one image, the button manipulates that image to indicate whether the button is disabled.

To assign images to tool buttons at design time

1. Select the toolbar on which the buttons appear.
2. In the **Object Inspector**, assign a *TImageList* object to the toolbar's *Images* property. An image list is a collection of same-sized icons or bitmaps.
3. Select a tool button.
4. In the **Object Inspector**, assign an integer to the tool button's *ImageIndex* property that corresponds to the image in the image list that you want to assign to the button.

You can also specify separate images to appear on the tool buttons when they are disabled and when they are under the mouse pointer. To do so, assign separate image lists to the toolbar's *DisabledImages* and *HotImages* properties.

3.2.4.5.17 Building Menus

You add a menu component to your form, or forms, for every menu you want to include in your application. You can build each menu structure entirely from scratch, or you can start from one of the predesigned menu templates.

For more information about menu templates, see Using menu templates (see page 2009).

For more information about creating a menu using the menu designer see

- Naming menus (see page 1991)

- Naming the menu items (see page 1991)
- Adding (see page 1968)
- Creating submenus (see page 1978)
- Adding images to menu items (see page 1967)
- Viewing the menu (see page 2011)

See Also

TMenu

Creating and Managing Menus (see page 1975)

3.2.4.5.18 Common Controls and XP Themes

Microsoft has forked Windows common controls into two separate versions. Version 5 is available on all Windows versions from Windows 95 or later; it displays controls using a "3D chiseled" look. Version 6 became available with Windows XP. Under version 6, controls are rendered by a theme engine which matches the current Windows XP theme. If the user changes the theme, version 6 common controls will match the new theme automatically. You don't need to recompile the application.

The VCL can now accommodate both types of common controls. CodeGear has added a number of components to the VCL to handle common control issues automatically and transparently. These components will be present in any VCL application you build. By default, any VCL applications will display version 5 common controls. To display version 6 controls, you (or your application's users) must add a manifest file to your application.

A manifest file contains an XML list of dependencies for your application. The file itself shares the name of your application, with ".manifest" appended to the end. For example, if your project creates Project1.exe as its executable, its manifest file should be named Project1.exe.manifest. Here is an example of a manifest file:

```
<?xml version="1.0" encoding="UTF-8" standalone="yes"?>
<assembly xmlns="urn:schemas-microsoft-com:asm.v1" manifestVersion="1.0">
<assemblyIdentity
version="1.0.0.0"
processorArchitecture="X86"
name="CompanyName.ProductName.YourApp"
type="win32"
/>
<description>Your application description here.</description>
<dependency>
<dependentAssembly>
<assemblyIdentity
type="win32"
name="Microsoft.Windows.Common-Controls"
version="6.0.0.0"
processorArchitecture="X86"
publicKeyToken="6595b64144ccf1df"
language="*"
/>
</dependentAssembly>
</dependency>
</assembly>
```

Use the example above to create a manifest file for your application. If you place your manifest file in the same directory as your application, its controls will be rendered using the common controls version 6 theme engine. Your application now supports Windows XP themes.

For more information on Windows XP common controls, themes, and manifest files, consult Microsoft's online documentation.

3.2.4.5.19 Controlling When Forms Reside in Memory

By default, Delphi automatically creates the application's main form in memory by including the following code in the application's main entry point:

```
Application.CreateForm(TForm1, Form1);
Application ->CreateForm(__classid(TForm1), &Form1);
```

This function creates a global variable with the same name as the form. So, every form in an application has an associated global variable. This variable is a pointer to an instance of the form's class and is used to reference the form while the application is running. Any unit that includes the form's unit in its **uses** clause can access the form via this variable.

All forms created in this way in the project unit appear when the program is invoked and exist in memory for the duration of the application.

3.2.4.5.20 Creating and Managing Menus

Menus provide an easy way for your users to execute logically grouped commands. The Menu Designer enables you to easily add a menu—either predesigned or custom tailored—to your form. You add a menu component to the form, open the Menu Designer, and type menu items directly into the Menu Designer window. You can add or delete menu items, or drag and drop them to rearrange them during design time.

You don't even need to run your program to see the results—your design is immediately visible in the form, appearing just as it will during runtime. Your code can also change menus at runtime, to provide more information or options to the user.

This topic explains how to use the Menu Designer to design menu bars and pop-up (local) menus. It discusses the following ways to work with menus at design time and runtime:

- Opening the Menu Designer (see page 1992).
- Building menus (see page 1973).
- Editing menu items in the Object Inspector (see page 1983).
- Using the Menu Designer context menu (see page 2010).
- Using menu templates (see page 2009).
- Saving a menu as a template (see page 2001).
- Adding images to menu items (see page 1967).

For information about hooking up menu items to the code that executes when they are selected, see .

See Also

Associating Menu Events with Event Handlers (see page 2144)

3.2.4.5.21 Creating and Using Component Templates

You can create templates that are made up of one or more components. After arranging components on a form, setting their properties, and writing code for them, save them as a *component template*. Later, by selecting the template from the **Tool palette**, you can place the preconfigured components on a form in a single step; all associated properties and event-handling code are added to your project at the same time.

Once you place a template on a form, you can reposition the components independently, reset their properties, and create or modify event handlers for them just as if you had placed each component in a separate operation.

To create a component template:

1. Place and arrange components on a form. In the **Object Inspector**, set their properties and events as desired.
2. Select the components. The easiest way to select several components is to drag the mouse over all of them. Gray handles appear at the corners of each selected component.
3. Choose **Component ▸ Create Component Template**.
4. Specify a name for the component template in the Component Template Information edit box. The default proposal is the component type of the first component selected in step 2 followed by the word "Template." For example, if you select a label and then an edit box, the proposed name will be "TLabelTemplate." You can change this name, but be careful not to duplicate existing component names.
5. In the Palette page edit box, specify the **Tool palette** page where you want the template to reside. If you specify a page that does not exist, a new page is created when you save the template.
6. Next to Palette Icon, select a bitmap to represent the template on the palette. The default proposal will be the bitmap used by the component type of the first component selected in step 2. To browse for other bitmaps, click Change. The bitmap you choose must be no larger than 24 pixels by 24 pixels.
7. Click OK.

To remove templates from the **Tool palette**, choose **Component ▸ Configure Palette**.

Reusing Components and Groups of Components (see page 2000)

3.2.4.5.22 Creating Customizable Toolbars and Menus

You can use action bands with the Action Manager to create customizable toolbars and menus. At runtime, users of your application can customize the toolbars and menus (action bands) in the application user interface using a customization dialog similar to the Action Manager editor.

To allow the user of your application to customize an action band in your application:

1. Drop an Action Manager component onto a form.
2. Drop your action band components (TCustomActionMainMenuBar,TActionToolBar).
3. Double-click the Action Manager to display the Action Manager editor:

- Add the actions you want to use in your application. Also add the Customize action, which appears at the bottom of the standard actions list.
- Drop a *TCustomizeDlg* component from the Additional tab onto the form, and connect it to the Action Manager using its ActionManager property. You specify a filename for where to stream customizations made by users.
- Drag and drop the actions onto the action band components. (Make sure you add the Customize action to the toolbar or menu.)

4. Complete your application.

When you compile and run the application, users can access a Customize command that displays a customization dialog box similar to the Action Manager editor. They can drag and drop menu items and create toolbars using the same actions you supplied in the Action Manager.

3.2.4.5.24 Creating Frames

To create an empty frame, choose **File** ▸ **New** ▸ **Delphi Projects** ▸ **Delphi Files** and double-click Frame. You can then drop components (including other frames) onto your new frame.

It is usually best—though not necessary—to save frames as part of a project. If you want to create a project that contains only frames and no forms, choose **File** ▸ **New** ▸ **Application**, close the new form and unit without saving them, then choose **File** ▸ **New** ▸ **Delphi Projects** ▸ **Delphi Files** ▸ **Frame** and save the project.

Note: When you save frames, avoid using the default names *Unit1*, *Project1*, and so forth, since these are likely to cause conflicts when you try to use the frames later.

At design time, you can display any frame included in the current project by choosing **View** ▸ **Forms** and selecting a frame. As with forms and data modules, you can toggle between the Form Designer and the frame's form file by right-clicking and choosing View as Form or View as Text.

Adding frames to the Tool palette

Frames are added to the **Tool palette** as component templates. To add a frame to the **Tool palette**, open the frame in the Form Designer (you cannot use a frame embedded in another component for this purpose), right-click the frame, and choose Add to Palette. When the Component Template Information dialog opens, select a name, palette page, and icon for the new template.

See Also

Working with Frames (see page 2012)

Using and Modifying Frames (see page 2008)

Sharing Frames (see page 2005)

Creating and Using Component Templates (see page 1975)

3.2.4.5.25 Creating Most Recently Used Lists

A most recently used list (MRU) reflects the user's most recently accessed files in a specific application. Using action bands, you can code MRU lists in your applications.

When building MRUs for your applications, it is important not to hard code references to specific numerical indexes into the Action Manager's *ActionBars* property. At runtime, the user may change the order of items or even delete them from the action

bands, which in turn will change the numerical ordering of the index. Instead of referring to index numbering, *TActionManager* includes methods that facilitate finding items by action or by caption.

For more information about MRU lists, sample code, and methods for finding actions in lists, see FindItemByAction and FindItemByCaption in the online Help.

See Also

TActionManager

TActionBars

TActionClients

TActionClientItem

3.2.4.5.26 Creating Submenus

Many application menus contain drop-down lists that appear next to a menu item to provide additional, related commands. Such lists are indicated by an arrow to the right of the menu item. Delphi supports as many levels of such submenus as you want to build into your menu.

Organizing your menu structure this way can save vertical screen space. However, for optimal design purposes you probably want to use no more than two or three menu levels in your interface design. (For pop-up menus, you might want to use only one submenu, if any.)

To create a submenu:

1. Select the menu item under which you want to create a submenu.
2. Press `Ctrl+RIGHT ARROW` to create the first placeholder, or right-click and choose Create Submenu.
3. Type a name for the submenu item, or drag an existing menu item into this placeholder.
4. Press `ENTER`, or `DOWN ARROW`, to create the next placeholder.
5. Repeat steps 3 and 4 for each item you want to create in the submenu.
6. Press `ESC` to return to the previous menu level.

Creating submenus by demoting existing menus

You can create a submenu by inserting a menu item from the menu bar (or a menu template) between menu items in a list. When you move a menu into an existing menu structure, all its associated items move with it, creating a fully intact submenu. This pertains to submenus as well. Moving a menu item into an existing submenu just creates one more level of nesting.

See Also

Creating and Managing Menus (see page 1975)

Moving Menu Items (see page 1990)

3.2.4.5.27 Creating Toolbars and Menus

Note: This topic describes the recommended method for creating menus and toolbars in Windows applications. For cross-platform development, you need to use *TToolBar* and the menu components, such as *TMainMenu,* organizing them using action lists (*TActionList*). See Setting up action lists (see page 2003) for details.

You use the Action Manager to automatically generate toolbars and main menus based on the actions contained in your application. The Action Manager manages standard actions and any custom actions that you have written. You then create UI elements based on these actions and use action bands to render the actions items as either menu items or as buttons on a toolbar.

The general procedure for creating menus, toolbars, and other action bands involves these steps:

- Drop an Action Manager onto a form.
- Add actions to the Action Manager, which organizes them into appropriate action lists.
- Create the action bands (that is, the menu or the toolbar) for the user interface.
- Drag and drop the actions into the application interface.

The following procedure explains these steps in more detail.

To create menus and toolbars using action bands:

1. From the Additional category of the **Tool palette**, drop an Action Manager component (TActionManager) onto the form where you want to create the toolbar or menu.
2. If you want images on the menu or toolbar, drop an ImageList component from the Win32 category of the **Tool palette** onto a form. (You need to add the images you want to use to the ImageList or use the one provided.)
3. From the Additional category of the **Tool palette**, drop one or more of the following action bands onto the form:

- TCustomActionMainMenuBar*(for designing main menus)*
- *TActionToolBar(for designing toolbars)*

4. Connect the ImageList to the Action Manager: with focus on the Action Manager and in the **Object Inspector**, select the name of the ImageList from the Images property.
5. Add actions to the Action Manager editor's action pane:

- Double-click the Action Manager to display the Action Manager editor.
- Click the drop-down arrow next to the New Action button (the leftmost button at the top right corner of the Actions tab) and select New Action or New Standard Action. A tree view is displayed. Add one or more actions or categories of actions to the Action Manager's actions pane. The Action Manager adds the actions to its action lists.

6. Drag and drop single actions or categories of actions from the Action Manager editor onto the menu or toolbar you are designing.

To add user-defined actions, create a new *TAction* by pressing the New Action button and writing an event handler that defines how it will respond when fired. See What happens when an action fires (see page 1984) for details. Once you've defined the actions, you can drag and drop them onto menus or toolbars like the standard actions.

Setting Up Action Lists (see page 2003)

3.2.4.5.28 Creating a Group of Speed Buttons

A series of speed buttons often represents a set of mutually exclusive choices. In that case, you need to associate the buttons into a group, so that clicking any button in the group causes the others in the group to pop up.

To associate any number of speed buttons into a group, assign the same number to each speed button's *GroupIndex* property.

The easiest way to do this is to select all the buttons you want in the group, and, with the whole group selected, set *GroupIndex* to a unique value.

TToolBar

TCoolBar

TPanel

TToolButton

TSpeedButton

3.2.4.5.29 Creating Forms Dynamically

You may not always want all your application's forms in memory at once. To reduce the amount of memory required at load time, you may want to create some forms only when you need to use them. For example, a dialog box needs to be in memory only during the time a user interacts with it.

To create a form at a different stage during execution using the IDE:

1. Select the **File** ▸ **New** ▸ **Form** from the main menu to display the new form.
2. Remove the form from the Auto-create forms list of the **Project** ▸ **Options** ▸ **Forms** page. This removes the form's invocation at startup. As an alternative, you can manually remove the following line from program's main entry point:

```
Application.CreateForm(TResultsForm, ResultsForm);
Application->CreateForm(__classid(TResultsForm), &ResultsForm);
```

3. Invoke the form when desired by using the form's *Show* method, if the form is modeless, or *ShowModal* method, if the form is modal.

An event handler for the main form must create an instance of the result form and destroy it. One way to invoke the result form is to use the global variable as follows. Note that *ResultsForm* is a modal form so the handler uses the *ShowModal* method.

```
procedure TMainForm.Button1Click(Sender: TObject);
begin
  ResultsForm := TResultForm.Create(self);
  try
    ResultsForm.ShowModal;
  finally
    ResultsForm.Free;
  end;
end;
void __fastcall TMainMForm::FirstButtonClick(TObject *Sender)
{
ResultsForm = new TResultsForm(this);
ResultsForm->ShowModal();
delete ResultsForm;
}
```

In the above example, note the use of **try..finally**. Putting in the line ResultsForm.Free; in the **finally** clause ensures that the memory for the form is freed even if the form raises an exception.

The event handler in the example deletes the form after it is closed, so the form would need to be recreated if you needed to use *ResultsForm* elsewhere in the application. If the form were displayed using *Show* you could not delete the form within the event handler because *Show* returns while the form is still open.

Note: If you create a form using its constructor, be sure to check that the form is not in the Auto-create forms list on the Project ->Options->Forms

page. Specifically, if you create the new form without deleting the form of the same name from the list, Delphi creates the form at startup and this event-handler creates a new instance of the form, overwriting the reference to the auto-created instance. The auto-created instance still exists, but the application can no longer access it. After the event-handler terminates, the global

variable no longer points to a valid form. Any attempt to use the global variable will likely crash the application.

See Also

TForm

3.2.4.5.30 Creating Groups of Tool Buttons

To create a group of tool buttons, select the buttons you want to associate and set their *Style* property to *tbsCheck*; then set their *Grouped* property to *True*. Selecting a grouped tool button causes other buttons in the group to pop up, which is helpful to represent a set of mutually exclusive choices.

Any unbroken sequence of adjacent tool buttons with *Style* set to *tbsCheck* and *Grouped* set to *True* forms a single group. To break up a group of tool buttons, separate the buttons with any of the following:

- A tool button whose *Grouped* property is *False*.
- A tool button whose *Style* property is not set to *tbsCheck*. To create spaces or dividers on the toolbar, add a tool button whose *Style* is *tbsSeparator* or *tbsDivider*.
- Another control besides a tool button.

3.2.4.5.31 Creating Modeless Forms Such as Windows

You must guarantee that reference variables for modeless forms exist for as long as the form is in use. This means that these variables should have global scope. In most cases, you use the global reference variable that was created when you made the form (the variable name that matches the name property of the form). If your application requires additional instances of the form, declare separate global variables for each instance.

3.2.4.5.33 Designing Toolbars and Cool Bars

A *toolbar* is a panel, usually across the top of a form (under the menu bar), that holds buttons and other controls. A *cool bar* (also called a rebar) is a kind of toolbar that displays controls on movable, resizable bands. If you have multiple panels aligned to the top of the form, they stack vertically in the order added.

You can put controls of any sort on a toolbar. In addition to buttons, you may want to put use color grids, scroll bars, labels, and so on.

You can add a toolbar to a form in several ways:

- Place a panel (*TPanel*) on the form and add controls (typically speed buttons) to it.
- Use a toolbar component (*TToolBar*) instead of *TPanel*, and add controls to it. *TToolBar* manages buttons and other controls, arranging them in rows and automatically adjusting their sizes and positions. If you use tool button (*TToolButton*) controls on the toolbar, *TToolBar* makes it easy to group the buttons functionally and provides other display options.
- Use a cool bar (*TCoolBar*) component and add controls to it. The cool bar displays controls on independently movable and resizable bands.

How you implement your toolbar depends on your application. The advantage of using the Panel component is that you have total control over the look and feel of the toolbar.

By using the toolbar and cool bar components, you are ensuring that your application has the look and feel of a Windows application because you are using the native Windows controls. If these operating system controls change in the future, your application could change as well. Also, since the toolbar and cool bar rely on common components in Windows, your application requires the COMCTL32.DLL. Toolbars and cool bars are not supported in WinNT 3.51 applications.

The following sections describe how to:

- Adding a toolbar using a panel component (see page 1969).
- Adding a toolbar using the toolbar component (see page 1970).
- Adding a cool bar component (see page 1968).
- Responding to clicks (see page 1996).
- Adding hidden toolbars (see page 1971).
- Hiding and showing toolbars (see page 1987).

3.2.4.5.34 Determining the Order of Merged Menu Items: GroupIndex Property

The *GroupIndex* property determines the order in which the merging menu items appear in the shared menu bar. Merging menu items can replace those on the main menu bar, or can be inserted.

The default value for *GroupIndex* is 0. Several rules apply when specifying a value for *GroupIndex*:

Rules	Description
Lower numbers appear first (farther left) in the menu.	For instance, set the *GroupIndex* property to 0 (zero) for a menu that you always want to appear leftmost, such as a File menu. Similarly, specify a high number (it needn't be in sequence) for a menu that you always want to appear rightmost, such as a Help menu.

To replace items in the main menu, give items on the child menu the same *GroupIndex* value.	This can apply to groupings or to single items. For example, if your main form has an Edit menu item with a *GroupIndex* value of 1, you can replace it with one or more items from the child form's menu by giving them a *GroupIndex* value of 1 as well. Giving multiple items in the child menu the same *GroupIndex* value keeps their order intact when they merge into the main menu.
To insert items without replacing items in the main menu, leave room in the numeric range of the main menu's items and "plug in" numbers from the child form.	For example, number the items in the main menu 0 and 5, and insert items from the child menu by numbering them 1, 2, 3, and 4.

3.2.4.5.35 Developing the Application User Interface: Overview

When you open the IDE or create a new project, a blank form is displayed on the screen. You design your application's user interface (UI) by placing and arranging visual components, such as windows, menus, and dialog boxes, from the **Tool palette** onto the form.

Once a visual component is on the form, you can adjust its position, size, and other design-time properties, and code its event handlers (see page 2149). The form takes care of the underlying programming details.

The following topics describe some of the major interface tasks, such as working with forms, creating component templates, adding dialog boxes, and organizing actions for menus and toolbars.

3.2.4.5.36 Displaying an Auto-created Form

If you choose to create a form at startup, and do not want it displayed until sometime later during program execution, the form's event handler uses the *ShowModal* method to display the form that is already loaded in memory:

```
procedure TMainForm.Button1Click(Sender: TObject);
begin
ResultsForm.ShowModal;
end;
void __fastcall TMainMForm::FirstButtonClick(TObject *Sender)
{
ResultsForm->ShowModal();
}
```

In this case, since the form is already in memory, there is no need to create another instance or destroy that instance.

TForm

3.2.4.5.37 Editing Menu Items in the Object Inspector

This topic has discussed how to set several properties for menu items—for example, the *Name* and *Caption* properties—by using the Menu Designer.

The section has also described how to set menu item properties, such as the *ShortCut* property, directly in the **Object Inspector**, just as you would for any component selected in the form.

When you edit a menu item by using the Menu Designer, its properties are still displayed in the **Object Inspector**. You can

switch focus to the **Object Inspector** and continue editing the menu item properties there. Or you can select the menu item from the Component list in the **Object Inspector** and edit its properties without ever opening the Menu Designer.

To close the Menu Designer window and continue editing menu items:

1. Switch focus from the Menu Designer window to the **Object Inspector** by clicking the properties page of the **Object Inspector**.
2. Close the Menu Designer as you normally would. The focus remains in the **Object Inspector**, where you can continue editing properties for the selected menu item. To edit another menu item, select it from the Component list.

3.2.4.5.38 What Happens When an Action Fires

When an event fires, a series of events intended primarily for generic actions occurs. Then if the event doesn't handle the action, another sequence of events occurs.

Responding with events

When a client component or control is clicked or otherwise acted on, a series of events occurs to which you can respond. For example, the following code illustrates the event handler for an action that toggles the visibility of a toolbar when the action is executed:

```
procedure TForm1.Action1Execute(Sender: TObject);
begin
{ Toggle Toolbar1's visibility }
ToolBar1.Visible := not ToolBar1.Visible;
end;
void __fastcall TForm1::Action1Execute(TObject *Sender)
{
// Toggle Toolbar1's visibility
ToolBar1->Visible = !ToolBar1->Visible;
}
```

Note: For general information about events and event handlers, see Working with Events and Event Handlers (see page 2149).

You can supply an event handler that responds at one of three different levels: the action, the action list, or the application. This is only a concern if you are using a new generic action rather than a predefined standard action. You do not have to worry about this if using the standard actions because standard actions have built-in behavior that executes when these events occur.

The order in which the event handlers will respond to events is as follows:

- Action list
- Application
- Action

When the user clicks on a client control, Delphi calls the action's Execute method which defers first to the action list, then the Application object, then the action itself if neither action list nor Application handles it. To explain this in more detail, Delphi follows this dispatching sequence when looking for a way to respond to the user action:

If you supply an *OnExecute* event handler for the action list and it handles the action, the application proceeds.

The action list's event handler has a parameter called Handled, that returns False by default. If the handler is assigned and it handles the event, it returns *True*, and the processing sequence ends here. For example:

```
procedure TForm1.ActionList1ExecuteAction(Action: TBasicAction; var Handled: Boolean);
begin
```

```
Handled := True;
end;
void __fastcall TForm1::ApplicationExecuteAction(TBasicAction *Action, bool &Handled)
{
  // Prevent execution of all actions in Application
Handled = true;
}
void __fastcall TForm1::ActionList1ExecuteAction(TBasicAction *Action, bool &Handled)
{
Handled = true;
}
```

If you don't set Handled to *True* in the action list event handler, then processing continues.

If you did not write an *OnExecute* event handler for the action list or if the event handler doesn't handle the action, the application's *OnActionExecute* event handler fires. If it handles the action, the application proceeds.

The global Application object receives an OnActionExecute event if any action list in the application fails to handle an event. Like the action list's *OnExecute* event handler, the *OnActionExecute* handler has a parameter Handled that returns *False* by default. If an event handler is assigned and handles the event, it returns *True*, and the processing sequence ends here. For example:

```
procedure TForm1.ApplicationExecuteAction(Action: TBasicAction; var Handled: Boolean);
begin
{ Prevent execution of all actions in Application }
Handled := True;
end;
```

If the application's *OnExecute* event handler doesn't handle the action, the action's *OnExecute* event handler fires.

You can use built-in actions or create your own action classes that know how to operate on specific target classes (such as edit controls). When no event handler is found at any level, the application next tries to find a target on which to execute the action. When the application locates a target that the action knows how to address, it invokes the action. See how actions find their targets (see page 1987) for details on how the application locates a target that can respond to a predefined action class.

Using Action Lists (see page 2007)

3.2.4.5.39 Handling the Screen

A global variable of type *TScreen* called *Screen* is created when you create a project. Screen encapsulates the state of the screen on which your application is running. Common tasks performed by *Screen* include specifying:

- The look of the cursor.
- The size of the window in which your application is running.
- A list of fonts available to the screen device.
- Multiple screen behavior (Windows only).

If your Windows application runs on multiple monitors, *Screen* maintains a list of monitors and their dimensions so that you can effectively manage the layout of your user interface.

See Also

TScreen

3.2.4.5.40 Hiding the Main Form

You can prevent the main form from appearing when your application starts by using the global Application variable (see page 2012).

To hide the main form at startup:

1. Choose **Project** ▸ **View Source** to display the main project file.
2. Add the following code after the call to Application.CreateForm and before the call to Application.Run.

```
Application.ShowMainForm := False;
Form1.Visible := False; { the name of your main form may differ }
Application->ShowMainForm = false;
```

Note: You can set the form's *Visible* property to *False* using the Object Inspector

at design time rather than setting it at runtime as in the previous example.

See Also

ShowMainForm

Application

Using the Main Form (see page 2009)

3.2.4.5.41 Hiding Unused Items and Categories in Action Bands

One benefit of using ActionBands is that unused items and categories can be hidden from the user. Over time, the action bands become customized for the application users, showing only the items that they use and hiding the rest from view. Hidden items can become visible again when the user presses a drop-down button. Also, the user can restore the visibility of all action band items by resetting the usage statistics from the customization dialog. Item hiding is the default behavior of action bands, but that behavior can be changed to prevent hiding of individual items, all the items in a particular collection (like the File menu), or all of the items in a given action band.

The action manager keeps track of the number of times an action has been called by the user, which is stored in the associated *TActionClientItem's UsageCount* field. The action manager also records the number of times the application has been run, which we shall call the session number, as well as the session number of the last time an action was used. The value of *UsageCount* is used to look up the maximum number of sessions the item can go unused before it becomes hidden, which is then compared with the difference between the current session number and the session number of the last use of the item. If that difference is greater than the number determined in *PrioritySchedule*, the item is hidden. The default values of *PrioritySchedule* are shown in the table below:

Default values of the action manager's PrioritySchedule property

Number of sessions in which an action band item was used	Number of sessions an item will remain unhidden after its last use
0, 1	3
2	6
3	9
4, 5	12
6-8	17
9-13	23
14-24	29

25 or more	31

It is possible to disable item hiding at design time. To prevent a specific action (and all the collections containing it) from becoming hidden, find its *TActionClientItem* object and set its *UsageCount* to -1. To prevent hiding for an entire collection of items, such as the File menu or even the main menu bar, find the *TActionClients* object associated with the collection and set its *HideUnused* property to *False*.

3.2.4.5.42 Hiding and Showing Toolbars

Often, you want an application to have multiple toolbars, but you do not want to clutter the form with them all at once. Or you may want to let users decide whether to display toolbars. As with all components, toolbars can be shown or hidden at runtime as needed.

To show or hide a toolbar at runtime, set its *Visible* property to *False* or *True*, respectively. Usually you do this in response to particular user events or changes in the operating mode of the application. To do this, you typically have a close button on each toolbar. When the user clicks that button, the application hides the corresponding toolbar.

You can also provide a means of toggling the toolbar. In the following example, a toolbar of pens is toggled from a button on the main toolbar. Since each click presses or releases the button, an *OnClick* event handler can show or hide the Pen toolbar depending on whether the button is up or down.

```
procedure TForm1.PenButtonClick(Sender: TObject);
begin
  PenBar.Visible := PenButton.Down;
end;
void __fastcall TForm1::PenButtonClick(TObject *Sender)
{
  PenBar->Visible = PenButton->Down;
}
```

3.2.4.5.43 How Actions Find Their Targets

What happens when an action fires (see page 1984) describes the execution cycle that occurs when a user invokes an action. If no event handler is assigned to respond to the action, either at the action list, application, or action level, then the application tries to identify a target object to which the action can apply itself.

The application looks for the target using the following sequence:

1. Active control: The application looks first for an active control as a potential target.
2. Active form: If the application does not find an active control or if the active control can't act as a target, it looks at the screen's ActiveForm.
3. Controls on the form: If the active form is not an appropriate target, the application looks at the other controls on the active form for a target.

If no target is located, nothing happens when the event is fired.

Some controls can expand the search to defer the target to an associated component; for example, data-aware controls defer to the associated dataset component. Also, some predefined actions do not use a target; for example, the File Open dialog.

3.2.4.5.44 Developing Dialog Boxes

The dialog box components on the Dialogs category of the **Tool palette** make various dialog boxes available to your applications. These dialog boxes provide applications with a familiar, consistent interface that enables the user to perform common file operations such as opening, saving, and printing files. Dialog boxes display and/or obtain data.

Each dialog box opens when its *Execute* method is called. *Execute* returns a Boolean value: if the user chooses OK to accept any changes made in the dialog box, *Execute* returns *True*; if the user chooses Cancel to escape from the dialog box without making or saving changes, *Execute* returns *False*.

3.2.4.5.45 Importing Resource Files

You can build menus with other applications, so long as the menus are in the standard Windows resource (.RC) file format. You can import such menus directly into your project, saving you the time and effort of rebuilding menus that you created elsewhere.

To load existing .RC menu files

1. In the Menu Designer, place your cursor where you want the menu to appear. The imported menu can be part of a menu you are designing, or an entire menu in itself.
2. Right-click and choose Insert From Resource. The Insert Menu From Resource dialog box appears.
3. In the dialog box, select the resource file you want to load, and choose OK. The menu appears in the Menu Designer window.

   Note: If your resource file contains more than one menu, you first need to save each menu as a separate resource file before importing it.

See Also

TMenu

3.2.4.5.46 Managing Layout

At its simplest, you control the layout of your user interface by where you place controls in your forms. The placement choices you make are reflected in the control's *Top*, *Left*, *Width*, and *Height* properties. You can change these values at runtime to change the position and size of the controls in your forms.

Controls have a number of other properties, however, that allow them to automatically adjust to their contents or containers. This allows you to lay out your forms so that the pieces fit together into a unified whole.

Two properties affect how a control is positioned and sized in relation to its parent. The *Align* property lets you force a control to fit perfectly within its parent along a specific edge or filling up the entire client area after any other controls have been aligned. When the parent is resized, the controls aligned to it are automatically resized and remain positioned so that they fit against a particular edge.

If you want to keep a control positioned relative to a particular edge of its parent, but don't want it to necessarily touch that edge or be resized so that it always runs along the entire edge, you can use the *Anchors* property.

If you want to ensure that a control does not grow too big or too small, you can use the *Constraints* property. *Constraints* lets you specify the control's maximum height, minimum height, maximum width, and minimum width. Set these to limit the size (in pixels) of the control's height and width. For example, by setting the *MinWidth* and *MinHeight* of the constraints on a container object, you can ensure that child objects are always visible.

The value of *Constraints* propagates through the parent/child hierarchy so that an object's size can be constrained because it contains aligned children that have size constraints. *Constraints* can also prevent a control from being scaled in a particular dimension when its *ChangeScale* method is called.

TControl introduces a protected event, *OnConstrainedResize*, of type *TConstrainedResizeEvent*:

```
TConstrainedResizeEvent = procedure(Sender: TObject; var MinWidth, MinHeight, MaxWidth,
MaxHeight: Integer) of object;
void __fastcall (__closure *TConstrainedResizeEvent)(System::TObject* Sender, int &MinWidth,
int &MinHeight, int &MaxWidth, int &MaxHeight);
```

This event allows you to override the size constraints when an attempt is made to resize the control. The values of the constraints are passed as var parameters which can be changed inside the event handler. *OnConstrainedResize* is published for container objects (*TForm*, *TScrollBox*, *TControlBar*, and *TPanel*). In addition, component writers can use or publish this event for any descendant of *TControl*.

Controls that have contents that can change in size have an *AutoSize* property that causes the control to adjust its size to its font or contained objects.

3.2.4.5.47 Manipulating Menu Items at Runtime

Sometimes you want to add menu items to an existing menu structure while the application is running, to provide more information or options to the user. You can insert a menu item by using the menu item's *Add* or *Insert* method, or you can alternately hide and show the items in a menu by changing their *Visible* property. The *Visible* property determines whether the menu item is displayed in the menu. To dim a menu item without hiding it, use the Enabled property.

For examples that use the menu item's *Visible* and *Enabled* properties, see Disabling menu items (see page 2160).

In multiple document interface (MDI) and Object Linking and Embedding (OLE) applications, you can also merge menu items into an existing menu bar. See Merging menus (see page 1989) for more information.

See Also

TMenu

Creating and Managing Menus (see page 1975)

3.2.4.5.48 Merging Menus

For MDI applications, such as the text editor sample application, and for OLE client applications, your application's main menu needs to be able to receive menu items either from another form or from the OLE server object. This is often called *merging menus*. Note that OLE technology is limited to Windows applications only and is not available for use in cross-platform programming.

You prepare menus for merging by specifying values for two properties:

- *Menu*, a property of the form
- *GroupIndex*, a property of menu items in the menu

See Also

TMenu

3.2.4.5.49 Using Forms

When you create a form from the IDE, Delphi automatically creates the form in memory by including code in the main entry point of your application function. Usually, this is the desired behavior and you don't have to do anything to change it. That is, the main window persists through the duration of your program, so you would likely not change the default behavior when creating the form for your main window.

However, you may not want all your application's forms in memory for the duration of the program execution. That is, if you do not want all your application's dialogs in memory at once, you can create the dialogs dynamically when you want them to appear.

Forms can be modal or modeless. Modal forms are forms with which the user must interact before switching to another form (for example, a dialog box requiring user input). Modeless forms are windows that are displayed until they are either obscured by another window or until they are closed or minimized by the user.

See Also

TForm

3.2.4.5.50 Moving Menu Items

During design time, you can move menu items simply by dragging and dropping. You can move menu items along the menu bar, or to a different place in the menu list, or into a *different* menu entirely.

The only exception to this is hierarchical: you cannot demote a menu item from the menu bar into its own menu; nor can you move a menu item into its own submenu. However, you can move any item into a different menu, no matter what its original position is.

While you are dragging, the cursor changes shape to indicate whether you can release the menu item at the new location. When you move a menu item, any items beneath it move as well.

To move a menu item along the menu bar:

1. Drag the menu item along the menu bar until the arrow tip of the drag cursor points to the new location.
2. Release the mouse button to drop the menu item at the new location.

To move a menu item into a menu list:

1. Drag the menu item along the menu bar until the arrow tip of the drag cursor points to the new menu. This causes the menu to open, enabling you to drag the item to its new location.
2. Drag the menu item into the list, releasing the mouse button to drop the menu item at the new location.

See Also

TMenu

Creating and Managing Menus (see page 1975)

3.2.4.5.51 Naming Conventions for Template Menu Items and Event Handlers

When you save a menu as a template, Delphi does not save its *Name* property, since every menu must have a unique name

within the scope of its owner (the form). However, when you insert the menu as a template into a new form by using the Menu Designer, Delphi then generates new names for it and all of its items.

For example, suppose you save a File menu as a template. In the original menu, you name it *MyFile*. If you insert it as a template into a new menu, Delphi names it *File1*. If you insert it into a menu with an existing menu item named File1, Delphi names it *File2*.

Delphi also does not save any *OnClick* event handlers associated with a menu saved as a template, since there is no way to test whether the code would be applicable in the new form. When you generate a new event handler for the menu template item, Delphi still generates the event handler name. You can easily associate items in the menu template with existing *OnClick* event handlers in the form.

For more information, see Associating menu events with event handlers (see page 2144).

See Also

TMenu

3.2.4.5.52 Naming Menus

As with all components, when you add a menu component to the form, the form gives it a default name; for example, *MainMenu1*. You can give the menu a more meaningful name that follows language naming conventions.

The menu name is added to the form's type declaration, and the menu name then appears in the Component list.

See Also

TMenu

Creating and Managing Menus (see page 1975)

3.2.4.5.53 Naming the Menu Items

In contrast to the menu component itself, you need to explicitly name menu items as you add them to the form. You can do this in one of two ways:

- Directly type the value for the *Name* property.
- Type the value for the *Caption* property first, and let Delphi derive the *Name* property from the caption.

For example, if you give a menu item a *Caption* property value of File, Delphi assigns the menu item a *Name* property of *File1*. If you fill in the *Name* property before filling in the *Caption* property, Delphi leaves the *Caption* property blank until you type a value.

Note: If you enter characters in the *Caption* property that are not valid for Delphi identifiers, Delphi modifies the *Name* property accordingly. For example, if you want the caption to start with a number, Delphi precedes the number with a character to derive the *Name* property.

The following table demonstrates some examples of this, assuming all menu items shown appear in the same menu bar.

Sample captions and their derived names

Component caption	Derived name	Explanation
&File	File1	Removes ampersand
&File (2nd occurrence)	File2	Numerically orders duplicate items
1234	N12341	Adds a preceding letter and numerical order
1234 (2nd occurrence)	N12342	Adds a number to disambiguate the derived name
$@@@#	N1	Removes all non-standard characters, adding preceding letter and numerical order

• (hyphen)	N2	Numerical ordering of second occurrence of caption with no standard characters

As with the menu component, Delphi adds any menu item names to the form's type declaration, and those names then appear in the Component list.

See Also

TMenu

Creating and Managing Menus (see page 1975)

3.2.4.5.54 Opening the Menu Designer

You design menus for your application using the Menu Designer. Before you can start using the Menu Designer, first add either a *TMainMenu* or *TPopupMenu* component to your form. Both menu components are located on the Standard category of the **Tool palette**.

A MainMenu component creates a menu that's attached to the form's title bar. A PopupMenu component creates a menu that appears when the user right-clicks in the form. Pop-up menus do not have a menu bar.

To open the Menu Designer, select a menu component on the form, and then either:

- Double-click the menu component.
- Or, from the Properties page of the **Object Inspector**, select the Items property, and then either double-click [Menu] in the Value column, or click the ellipsis (...) button.

The Menu Designer appears, with the first (blank) menu item highlighted in the Designer, and the *Caption* property selected in the **Object Inspector**.

See Also

TMenu

Creating and Managing Menus (see page 1975)

3.2.4.5.55 Organizing Actions for Toolbars and Menus

Several features simplify the work of creating, customizing, and maintaining menus and toolbars. These features allow you to organize lists of actions that users of your application can initiate by pressing a button on a toolbar, choosing a command on a menu, or pointing and clicking on an icon.

Often a set of actions is used in more than one user interface element. For example, the Cut, Copy, and Paste commands often appear on both an Edit menu and on a toolbar. You only need to add the action once to use it in multiple UI elements in your application.

On the Windows platform, tools are provided to make it easy to define and group actions, create different layouts, and customize menus at design time or runtime. These tools are known collectively as ActionBand tools, and the menus and toolbars you create with them are known as action bands. In general, you can create an ActionBand user interface as follows:

- Build the action list to create a set of actions that will be available for your application (use the Action Manager, TActionManager)
- Add the user interface elements to the application (use ActionBand components such as TActionMainMenuBarand TActionToolBar)

- Drag-and-drop actions from the Action Manager onto the user interface elements

The following table defines the terminology related to setting up menus and toolbars:

Action setup terminology

Term	Definition
Action	A response to something a user does, such as clicking a menu item. Many standard actions that are frequently required are provided for you to use in your applications as is. For example, file operations such as File Open, File SaveAs, File Run, and File Exit are included along with many others for editing, formatting, searches, help, dialogs, and window actions. You can also program custom actions and access them using action lists and the Action Manager.
Action band	A container for a set of actions associated with a customizable menu or toolbar. The ActionBand components for main menus and toolbars (*TActionMainMenuBar* and *TActionToolBar*) are examples of action bands.
Action category	Lets you group actions and drop them as a group onto a menu or toolbar. For example, one of the standard action categories is Search which includes Find, FindFirst, FindNext, and Replace actions all at once.
Action classes	Classes that perform the actions used in your application. All of the standard actions are defined in action classes such as *TEditCopy*, *TEditCut*, and *TEditUndo*. You can use these classes by dragging and dropping them from the Customize dialog onto an action band.
Action client	Most often represents a menu item or a button that receives a notification to initiate an action. When the client receives a user command (such as a mouse click), it initiates an associated action.
Action list	Maintains a list of actions that your application can take in response to something a user does.
Action Manager	Groups and organizes logical sets of actions that can be reused on ActionBand components. See *TActionManager*.
Menu	Lists commands that the user of the application can execute by clicking on them. You can create menus by using the ActionBand menu class *TActionMainMenuBar*, or by using cross-platform components such as *TMainMenu* or *TPopupMenu*.
Target	Represents the item an action does something to. The target is usually a control, such as a memo or a data control. Not all actions require a target. For example, the standard help actions ignore the target and simply launch the help system.
Toolbar	Displays a visible row of button icons which, when clicked, cause the program to perform some action, such as printing the current document. You can create toolbars by using the ActionBand toolbar component *TActionToolBar*, or by using the cross-platform component *TToolBar*.

If you are doing cross-platform development, refer to Using action lists (see page 2007) for details.

TActionLink

Setting Up Action Lists (see page 2003)

3.2.4.5.56 Passing Additional Arguments to Forms

Typically, you create forms for your application from within the IDE. When created this way, the forms have a constructor that takes one argument, *Owner*, which is the owner of the form being created. (The owner is the calling application object or form object.) *Owner* can be **nil**.

To pass additional arguments to a form, create a separate constructor and instantiate the form using this new constructor. The

example form class below shows an additional constructor, with the extra argument *whichButton*. This new constructor is added to the form class manually.

```
TResultsForm = class(TForm)
  ResultsLabel: TLabel;
  OKButton: TButton;
  procedure OKButtonClick(Sender: TObject);
private
public
  constructor CreateWithButton(whichButton: Integer; Owner: TComponent);
end;
class TResultsForm : public TForm
{
__published:    // IDE-managed Components
TLabel *ResultsLabel;
TButton *OKButton;
void __fastcall OKButtonClick(TObject *Sender);
private:        // User declarations
public:         // User declarations
virtual __fastcall TResultsForm(TComponent* Owner);
   virtual __fastcall TResultsForm(int whichButton, TComponent* Owner);
};
```

Here's the manually coded constructor that passes the additional argument, *whichButton*. This constructor uses the *whichButton* parameter to set the *Caption* property of a *Label* control on the form.

```
constructor CreateWithButton(whichButton: Integer; Owner: TComponent);
begin
  inherited Create(Owner);
  case whichButton of
    1: ResultsLabel.Caption := "You picked the first button.";
    2: ResultsLabel.Caption := "You picked the second button.";
    3: ResultsLabel.Caption := "You picked the third button.";
  end;
end;
void__fastcall TResultsForm::TResultsForm(int whichButton, TComponent* Owner)
: TForm(Owner)
{
switch (whichButton) {
case 1:
ResultsLabel->Caption = "You picked the first button!";
break;
case 2:
ResultsLabel->Caption = "You picked the second button!";
break;
case 3:
ResultsLabel->Caption = "You picked the third button!";
}
}
```

When creating an instance of a form with multiple constructors, you can select the constructor that best suits your purpose. For example, the following *OnClick* handler for a button on a form calls creates an instance of *TResultsForm* that uses the extra parameter:

```
procedure TMainForm.SecondButtonClick(Sender: TObject);
var
  rf: TResultsForm;
begin
  rf := TResultsForm.CreateWithButton(2, self);
  rf.ShowModal;
  rf.Free;
end;
void __fastcall TMainMForm::SecondButtonClick(TObject *Sender)
{
TResultsForm *rf = new TResultsForm(2, this);
rf->ShowModal();
```

```
delete rf;
}
```

3.2.4.5.57 Predefined Action Classes

You can add predefined actions to your application by right-clicking on the Action Manager and choosing New Standard Action. The New Standard Action Classes dialog box is displayed listing the predefined action classes and the associated standard actions. These are actions that are included with Delphi and they are objects that automatically perform actions. The predefined actions are organized within the following classes:

Class	Description
Edit	Standard edit actions: Used with an edit control target. *TEditAction* is the base class for descendants that each override the *ExecuteTarget* method to implement copy, cut, and paste tasks by using the clipboard.
Format	Standard formatting actions: Used with rich text to apply text formatting options such as bold, italic, underline, strikeout, and so on. *TRichEditAction* is the base class for descendants that each override the *ExecuteTarget* and *UpdateTarget* methods to implement formatting of the target.
Help	Standard Help actions: Used with any target. *THelpAction* is the base class for descendants that each override the *ExecuteTarget* method to pass the command onto a Help system.
Window	Standard window actions: Used with forms as targets in an MDI application. *TWindowAction* is the base class for descendants that each override the *ExecuteTarget* method to implement arranging, cascading, closing, tiling, and minimizing MDI child forms.
File	File actions: Used with operations on files such as File Open, File Run, or File Exit.
Search	Search actions: Used with search options. *TSearchAction* implements the common behavior for actions that display a modeless dialog where the user can enter a search string for searching an edit control.
Tab	Tab control actions: Used to move between tabs on a tab control such as the Prev and Next buttons on a wizard.
List	List control actions: Used for managing items in a list view.
Dialog	Dialog actions: Used with dialog components. *TDialogAction* implements the common behavior for actions that display a dialog when executed. Each descendant class represents a specific dialog.
Internet	Internet actions: Used for functions such as Internet browsing, downloading, and sending mail.
DataSet	DataSet actions: Used with a dataset component target. *TDataSetAction* is the base class for descendants that each override the *ExecuteTarget* and *UpdateTarget* methods to implement navigation and editing of the target. *TDataSetAction* introduces a *DataSource* property that ensures actions are performed on that dataset. If *DataSource* is nil, the currently focused data-aware control is used.
Tools	Tools: Additional tools such as *TCustomizeActionBars* for automatically displaying the customization dialog for action bands.

All of the action objects are described under the action object names in the online Help.

3.2.4.5.58 Registering Actions

When you write your own actions, you can register actions to enable them to appear in the Action List editor. You register and unregister actions by using the global routines in the Actnlist unit:

```
procedure RegisterActions(const CategoryName: string; const AClasses: array of
TBasicActionClass; Resource: TComponentClass);
procedure UnRegisterActions(const AClasses: array of TBasicActionClass);
extern PACKAGE void __fastcall UnRegisterActions(TMetaClass* const * AClasses, const int
AClasses_Size);
extern PACKAGE void __fastcall RegisterActions(const AnsiString CategoryName, TMetaClass*
const * AClasses, const int AClasses_Size, TMetaClass* Resource);
```

When you call RegisterActions, the actions you register appear in the Action List editor for use by your applications. You can supply a category name to organize your actions, as well as a *Resource* parameter that lets you supply default property values.

For example, the following code registers the standard actions with the IDE:

```
{ Standard action registration }
RegisterActions('', [TAction], nil);
RegisterActions('Edit', [TEditCut, TEditCopy, TEditPaste], TStandardActions);
RegisterActions('Window', [TWindowClose, TWindowCascade, TWindowTileHorizontal,
TWindowTileVertical, TWindowMinimizeAll, TWindowArrange], TStandardActions);
namespace MyAction
{
  void __fastcall PACKAGE Register()
  {
     // code goes here to register any components and editors
TMetaClass classes[2] = {__classid(TMyAction1), __classid(TMyAction2)};
RegisterActions("MySpecialActions", classes, 1, NULL);
}
}
```

When you call UnRegisterActions, the actions no longer appear in the Action List editor.

3.2.4.5.59 Responding to Clicks

When the user clicks a control, such as a button on a toolbar, the application generates an *OnClick* event which you can respond to with an event handler. Since *OnClick* is the default event for buttons, you can generate a skeleton handler for the event by double-clicking the button at design time. For general information about events and event handlers, see Working with Events and Event Handlers (see page 2149) and Generating a handler for a component's default event (see page 2147).

3.2.4.5.60 Retrieving Data from Forms

Most real-world applications consist of several forms. Often, information needs to be passed between these forms. Information can be passed to a form by means of parameters to the receiving form's constructor, or by assigning values to the form's properties. The way you get information from a form depends on whether the form is modal or modeless.

See Also

TForm

3.2.4.5.61 Retrieving Data from Modal Forms

Just like modeless forms, modal forms often contain information needed by other forms. The most common example is when form A launches modal form B. When form B is closed, form A needs to know what the user did with form B to decide how to proceed with the processing of form A. If form B is still in memory, it can be queried through properties or member functions just as in the modeless forms example above. But how do you handle situations where form B is deleted from memory upon closing? Since a form does not have an explicit return value, you must preserve important information from the form before it is destroyed.

To illustrate, consider a modified version of the *ColorForm* form that is designed to be a modal form. The class declaration is as follows:

```
TColorForm = class(TForm)
  ColorListBox:TListBox;
  SelectButton: TButton;
  CancelButton: TButton;
  procedure CancelButtonClick(Sender: TObject);
  procedure SelectButtonClick(Sender: TObject);
private
  FColor: Pointer;
public
  constructor CreateWithColor(Value: Pointer; Owner: TComponent);
end;
```

```
class TColorForm : public TForm
{
__published:    // IDE-managed Components
TListBox *ColorListBox;
TButton *SelectButton;
TButton *CancelButton;
void __fastcall CancelButtonClick(TObject *Sender);
void __fastcall SelectButtonClick(TObject *Sender);
private:        // User declarations
String* curColor;
public:         // User declarations
virtual __fastcall TColorForm(TComponent* Owner);
virtual __fastcall TColorForm(String* s, TComponent* Owner);
};
```

The form has a listbox called *ColorListBox* with a list of names of colors. When pressed, the button called *SelectButton* makes note of the currently selected color name in *ColorListBox* then closes the form. *CancelButton* is a button that simply closes the form.

Note that a user-defined constructor was added to the class that takes a *Pointer* argument. Presumably, this *Pointer* points to a string that the form launching *ColorForm* knows about. The implementation of this constructor is as follows:

```
constructor TColorForm(Value: Pointer; Owner: TComponent);
begin
  FColor := Value;
  String(FColor^) := '';
end;
```

```
void__fastcall TColorForm::TColorForm(String* s, TComponent* Owner)
: TForm(Owner)
```

```
{
curColor = s;
*curColor = "";
}
```

The constructor saves the pointer to a private data member *FColor* and initializes the string to an empty string.

Note: To use the above user-defined constructor, the form must be explicitly created. It cannot be auto-created when the application is started. For details, see Controlling when forms reside in memory (see page 1975).

In the application, the user selects a color from the listbox and presses *SelectButton* to save the choice and close the form. The *OnClick* event handler for *SelectButton* might look like this:

```
procedure TColorForm.SelectButtonClick(Sender: TObject);
begin
  with ColorListBox do
    if ItemIndex >= 0 then
      String(FColor^) := ColorListBox.Items[ItemIndex];
  end;
  Close;
end;
void __fastcall TColorForm::SelectButtonClick(TObject *Sender)
{
int index = ColorListBox->ItemIndex;
if (index >= 0)
*curColor = ColorListBox->Items->Strings[index];
Close();
}
```

Notice that the event handler stores the selected color name in the string referenced by the pointer that was passed to the constructor.

To use *ColorForm* effectively, the calling form must pass the constructor a pointer to an existing string. For example, assume *ColorForm* was instantiated by a form called *ResultsForm* in response to a button called *UpdateButton* on *ResultsForm* being clicked. The event handler would look as follows:

```
procedure TResultsForm.UpdateButtonClick(Sender: TObject);
var
  MainColor: String;
begin
  GetColor(Addr(MainColor));
  if MainColor <> '' then
    {do something with the MainColor string}
  else
    {do something else because no color was picked}
end;
procedure GetColor(PColor: Pointer);
begin
  ColorForm := TColorForm.CreateWithColor(PColor, Self);
  ColorForm.ShowModal;
  ColorForm.Free;
end;
void __fastcall TResultsForm::UpdateButtonClick(TObject *Sender)
{
String s;
GetColor(&s);
if (s != "") {
// do something with the color name string
}
else {
// do something else because no color was picked
}
}
//---------------------------------------------------------------------
void TResultsForm::GetColor(String *s)
{
```

```
ColorForm = new TColorForm(s, this);
ColorForm->ShowModal();
delete ColorForm;
ColorForm = 0; // NULL the pointer
}
```

UpdateButtonClick creates a String called MainColor. The address of MainColor is passed to the *GetColor* function which creates *ColorForm*, passing the pointer to MainColor as an argument to the constructor. As soon as *ColorForm* is closed it is deleted, but the color name that was selected is still preserved in MainColor, assuming that a color was selected. Otherwise, MainColor contains an empty string which is a clear indication that the user exited *ColorForm* without selecting a color.

This example uses one string variable to hold information from the modal form. Of course, more complex objects can be used depending on the need. Keep in mind that you should always provide a way to let the calling form know if the modal form was closed without making any changes or selections (such as having MainColor default to an empty string).

See Also

TForm

3.2.4.5.62 Retrieving Data from Modeless Forms

You can easily extract information from modeless forms by calling public member functions of the form or by querying properties of the form. For example, assume an application contains a modeless form called *ColorForm* that contains a listbox called *ColorListBox* with a list of colors ("Red," "Green," "Blue," and so on). The selected color name string in *ColorListBox* is automatically stored in a property called *CurrentColor* each time a user selects a new color. The class declaration for the form is as follows:

```
TColorForm = class(TForm)
  ColorListBox:TListBox;
  procedure ColorListBoxClick(Sender: TObject);
private
  FColor:String;
public
  property CurColor:String read FColor write FColor;
end;
class TColorForm : public TForm
{
__published:    // IDE-managed Components
TListBox *ColorListBox;
void __fastcall ColorListBoxClick(TObject *Sender);
private:        // User declarations
String getColor();
void   setColor(String);
String curColor;
public:         // User declarations
virtual __fastcall TColorForm(TComponent* Owner);
__property String CurrentColor = {read=getColor, write=setColor};
};
```

The *OnClick* event handler for the listbox, *ColorListBoxClick*, sets the value of the *CurrentColor* property each time a new item in the listbox is selected. The event handler gets the string from the listbox containing the color name and assigns it to *CurrentColor*. The *CurrentColor* property uses the setter function, *SetColor*, to store the actual value for the property in the private data member *FColor*:

```
procedure TColorForm.ColorListBoxClick(Sender: TObject);
var
  Index: Integer;
begin
  Index := ColorListBox.ItemIndex;
  if Index >= 0 then
    CurrentColor := ColorListBox.Items[Index]
  else
```

```
    CurrentColor := '';
end;
void __fastcall TColorForm::ColorListBoxClick(TObject *Sender)
{
int index = ColorListBox->ItemIndex;
if (index >= 0) {
CurrentColor = ColorListBox->Items->Strings[index];
}
else
CurrentColor = "";
}
//---------------------------------------------------------------------
void TColorForm::setColor(String s)
{
curColor = s;
}
```

Now suppose that another form within the application, called *ResultsForm*, needs to find out which color is currently selected on *ColorForm* whenever a button (called *UpdateButton*) on *ResultsForm* is clicked. The *OnClick* event handler for *UpdateButton* might look like this:

```
procedure TResultForm.UpdateButtonClick(Sender: TObject);
var
  MainColor: String;
begin
  if Assigned(ColorForm) then
  begin
    MainColor := ColorForm.CurrentColor;
    {do something with the string MainColor}
  end;
end;
void __fastcall TResultsForm::UpdateButtonClick(TObject *Sender)
{
if (ColorForm) {
String s = ColorForm->CurrentColor;
// do something with the color name string
}
}
```

The event handler first verifies that *ColorForm* exists using the *Assigned* function. It then gets the value of *ColorForm's CurrentColor* property.

Alternatively, if *ColorForm* had a public function named *GetColor*, another form could get the current color without using the *CurrentColor* property (for example, `MainColor := ColorForm.GetColor;`). In fact, there's nothing to prevent another form from getting the ColorForm's currently selected color by checking the listbox selection directly:

```
with ColorForm.ColorListBox do
  MainColor := Items[ItemIndex];
String TColorForm::getColor()
{
return curColor;
}
String s = ColorListBox->Items->Strings[ColorListBox->ItemIndex];
```

However, using a property makes the interface to *ColorForm* very straightforward and simple. All a form needs to know about *ColorForm* is to check the value of *CurrentColor*.

3.2.4.5.63 Reusing Components and Groups of Components

You can save and reuse work you've done with components using several tools:

- Configure and save groups of components in component templates (see page 1975).
- Save forms, data modules, and projects in the Object Repository (see page 1917). The Repository gives you a central database of reusable elements and lets you use form inheritance to propagate changes.
- Save frames (see page 2012) on the **Tool palette** or in the Repository. Frames use form inheritance and can be embedded into forms or other frames.
- Create a custom component (see page 1313), the most complicated but most flexible way of reusing code. See Overview of Component Creation (see page 1313).

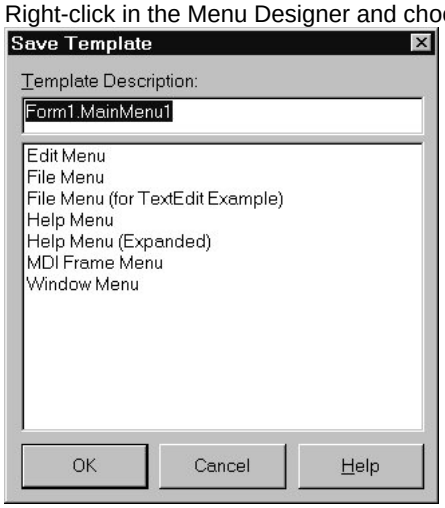
Developing the Application User Interface: Overview (see page 1983)



3.2.4.5.64 Saving a Menu as a Template

Any menu you design can be saved as a template so you can use it again. You can use menu templates to provide a consistent look to your applications, or use them as a starting point which you then further customize.

The menu templates you save are stored in your BIN subdirectory as .dmt files.

To save a menu as a template

1. Design the menu you want to be able to reuse. This menu can contain as many items, commands, and submenus as you like; everything in the active Menu Designer window will be saved as one reusable menu.
2. Right-click in the Menu Designer and choose Save As Template. The Save Template dialog box appears.

3. In the Template Description edit box, type a brief description for this menu, and then choose OK. The Save Template dialog box closes, saving your menu design and returning you to the Menu Designer window.

   Note: The description you enter is displayed only in the Save Template, Insert Template, and Delete Templates dialog boxes. It is not related to the *Name* or *Caption* property for the menu.

See Also

TMenu

3.2.4.5.65 Selecting Menu and Toolbar Styles

Just as you can add different colors and icons to individual menus and toolbars, you can select different menu and toolbar styles to give your application a comprehensive look and feel. In addition to the standard style, your application can take on the look of Windows XP, Encarta™, or a custom presentation using a coordinated color scheme. To give your application a coherent look and feel, the IDE uses colormaps.

A colormap can be simple, merely adding the appropriate colors to existing menus and toolbars. Or, a colormap can be complex, altering numerous subtle details of a menu's or toolbar's look and feel, including the smallest button edges or menu shadows. The XP colormap, for example, has numerous subtle refinements for menu and toolbar classes. The IDE handles the details for you, automatically using the appropriate colormaps.

By default, the component library uses the XP style. To centrally select an alternate style for all your application's menus and toolbars, use the *Style* property on the *ActionManager* component.

To select menu and toolbar styles:

1. From the Additional category of the **Tool palette**, drop an *ActionManager* component onto a form.
2. In the **Object Inspector**, select the *Style* property. You can choose from a number of different styles.
3. Once you've selected a style, your application's menus and toolbars will take on the look of the new colormap.

You can customize the look and feel of a style using colormap components.

To customize the look and feel of a colormap:

1. From the Additional category of the **Tool palette**, drop the appropriate colormap component onto a form (for example, *XPColorMap* or *StandardColorMap*). In the **Object Inspector**, you will see numerous properties to adjust appearance, many with drop downs from which you can select alternate values.
2. Change each ToolBar or menu's *ColorMap* property to point to the colormap object that you dropped on the form.
3. In the **Object Inspector**, adjust the colormap's properties to change the appearance of your toolbars and menus as desired.

   Note: Be careful when customizing a colormap. When you select a new, alternate colormap, your old settings will be lost. You may want to save a copy of your application if you want to experiment with alternate settings and possibly return to a previous customization.

3.2.4.5.66 Setting Up Action Bands

Because actions do not maintain any "layout" (either appearance or positional) information, Delphi provides action bands which are capable of storing this data. Action bands provide a mechanism that allows you to specify layout information and a set of controls. You can render actions as UI elements such as toolbars and menus.

You organize sets of actions using the Action Manager (TActionManager). You can use standard actions provided or create new actions of your own.

You then create the action bands:

- Use TActionMainMenuBar to create a main menu.
- Use TActionToolBarto create a toolbar.

The action bands act as containers that hold and render sets of actions. You can drag and drop items from the Action Manager editor onto the action band at design time. At runtime, application users can also customize the application's menus or toolbars using a dialog box similar to the Action Manager editor.

Setting Up Action Lists (see page 2003)

TActionList

TAction

TActionLink

TPopupMenu

3.2.4.5.67 Setting Up Action Lists

Setting up action lists is fairly easy once you understand the basic steps involved:

- Create the action list.
- Add actions to the action list.
- Set properties on the actions.
- Attach clients to the action.

Here are the steps in more detail:

1. Drop a *TActionList* object onto your form or data module. (ActionList is on the Standard category of the **Tool palette**.)
2. Double-click the *TActionList* object to display the Action List editor.

- Use one of the predefined actions listed in the editor: right-click and choose New Standard Action.
- The predefined actions are organized into categories (such as Dataset, Edit, Help, and Window) in the Standard Action Classes dialog box. Select all the standard actions you want to add to the action list and click OK.
- Or, create a new action of your own: right-click and choose New Action.

3. Set the properties of each action in the **Object Inspector**. (The properties you set affect every client of the action.) The Name property identifies the action, and the other properties and events (*Caption*, *Checked*, *Enabled*, *HelpContext*, *Hint*, *ImageIndex*, *ShortCut*, *Visible*, and *Execute*) correspond to the properties and events of its client controls. The client's corresponding properties are typically, but not necessarily, the same name as the corresponding client property. For example, an action's Enabled property corresponds to a *TToolButton's Enabled* property. However, an action's *Checked* property corresponds to a *TToolButton's Down* property.
4. If you use the predefined actions, the action includes a standard response that occurs automatically. If creating your own action, you need to write an event handler that defines how the action responds when fired. See What happens when an action fires (see page 1984) for details.
5. Attach the actions in the action list to the clients that require them:

- Click on the control (such as the button or menu item) on the form or data module. In the **Object Inspector**, the *Action* property lists the available actions.
- Select the one you want.

The standard actions, such as *TEditDelete* or *TDataSetPost*, all perform the action you would expect. You can look at the online reference Help for details on how all of the standard actions work if you need to. If writing your own actions, you'll need to understand more about what happens when the action is fired. See What happens when an action fires (see page 1984) for details.

Using Action Lists (see page 2007)

3.2.4.5.68 Setting the Appearance of the Cool Bar

The cool bar component offers several useful configuration options. The table below lists some actions you can set to change a tool button's appearance:

Setting a cool button's appearance

To make the cool bar:	Set the toolbar's:
Resize automatically to accommodate the bands it contains	*AutoSize* property to *True.*
Bands maintain a uniform height	*FixedSize* property to *True*.

Reorient to vertical rather than horizontal	*Vertical* property to *True*. This changes the effect of the *FixedSize* property.
Prevent the *Text* properties of the bands from displaying at runtime	*ShowText* property to *False*. Each band in a cool bar has its own *Text* property.
Remove the border around the bar	*BandBorderStyle* to *bsNone.*
Keep users from changing the bands' order at runtime. (The user can still move and resize the bands.)	*FixedOrder* to True.
Create a background image for the cool bar	*Bitmap* property to *TBitmap* object.
Choose a list of images to appear on the left of any band	*Images* property to *TImageList* object.

To assign images to individual bands, select the cool bar and double-click on the *Bands* property in the **Object Inspector**. Then select a band and assign a value to its *ImageIndex* property.

3.2.4.5.69 Setting the Initial Condition of a Speed Button

Speed buttons use their appearance to give the user clues as to their state and purpose. Because they have no caption, it's important that you use the right visual cues to assist users.

The table below lists some actions you can set to change a speed button's appearance:

Setting speed buttons' appearance

To make a speed button:	Set the toolbar's:
Appear pressed	*GroupIndex* property to a value other than zero and its *Down* property to *True*.
Appear disabled	*Enabled* property to *False*.
Have a left margin	*I*ndent property to a value greater than 0.

If your application has a default drawing tool, ensure that its button on the toolbar is pressed when the application starts. To do so, set its *GroupIndex* property to a value other than zero and its *Down* property to *True*.

TSpeedButton

3.2.4.5.70 Setting Tool Button Appearance and Initial Conditions

The table below lists some actions you can set to change a tool button's appearance:

Setting tool buttons' appearance

To make a tool button:	Set the toolbar's:
Appear pressed	(on tool button) *Style* property to *tbsCheck* and *Down* property to *True*.
Appear disabled	*Enabled* property to *False*.
Have a left margin	*I*ndent property to a value greater than 0.

Appear to have "pop-up" borders, thus making the toolbar appear transparent	*Flat* property to *True*.

Note: Using the *Flat* property of *TToolBar* requires version 4.70 or later of COMCTL32.DLL.

To force a new row of controls after a specific tool button, Select the tool button that you want to appear last in the row and set its *Wrap* property to True.

To turn off the auto-wrap feature of the toolbar, set the toolbar's *Wrapable* property to False.

3.2.4.5.71 Sharing Frames

You can share a frame with other developers in two ways:

- Add the frame to the Object Repository.
- Distribute the frame's unit (.pas) and form (.dfm or .xfm) files.

To add a frame to the Repository, open any project that includes the frame, right-click in the Form Designer, and choose Add to Repository. For more information, see Using the Object Repository (see page 1917).

If you send a frame's unit and form files to other developers, they can open them and add them to the **Tool palette**. If the frame has other frames embedded in it, they will have to open it as part of a project.

See Also

Working with Frames (see page 2012)

Using and Modifying Frames (see page 2008)

Creating Frames (see page 1977)

3.2.4.5.72 Specifying Accelerator Keys and Keyboard Shortcuts

Accelerator keys enable the user to access a menu command from the keyboard by pressing `Alt`+ the appropriate letter, indicated in your code by the preceding ampersand. The letter after the ampersand appears underlined in the menu.

Delphi automatically checks for duplicate accelerators and adjusts them at runtime. This ensures that menus built dynamically at runtime contain no duplicate accelerators and that all menu items have an accelerator. You can turn off this automatic checking by setting the *AutoHotkeys* property of a menu item to *maManual***.**

To specify an accelerator, add an ampersand in front of the appropriate letter. For example, to add a Save menu command with the S as an accelerator key, type `&Save`.

Keyboard shortcuts enable the user to perform the action without using the menu directly, by typing in the shortcut key combination.

To specify a keyboard shortcut, use the **Object Inspector** to enter a value for the ShortCut property, or select a key combination from the drop-down list. This list is only a subset of the valid combinations you can type in.

When you add a shortcut, it appears next to the menu item caption.

Warning: Keyboard shortcuts, unlike accelerator keys, are not checked automatically for duplicates. You must ensure uniqueness yourself.

TMenu

Creating and Managing Menus (see page 1975)

3.2.4.5.73 Specifying the Active Menu: Menu Property

The *Menu* property specifies the active menu for the form. Menu-merging operations apply only to the active menu. If the form contains more than one menu component, you can change the active menu at runtime by setting the *Menu* property in code. For example,

```
Form1.Menu := SecondMenu;
Form1->Menu = SecondMenu;
```

TMenu

3.2.4.5.74 Switching Between Menus at Design Time

If you're designing several menus for your form, you can use the Menu Designer context menu or the **Object Inspector** to easily select and move among them.

To use the context menu to switch between menus in a form:

1. Right-click in the Menu Designer and choose Select Menu. The Select Menu dialog box appears.

This dialog box lists all the menus associated with the form whose menu is currently open in the Menu Designer.

2. From the list in the Select Menu dialog box, choose the menu you want to view or edit.

To use the Object Inspector to switch between menus in a form:

1. Give focus to the form whose menus you want to choose from.
2. From the Component list, select the menu you want to edit.
3. On the Properties page of the **Object Inspector**, select the *Items* property for this menu, and then either click the ellipsis button, or double-click [Menu].

TMenu

3.2.4.5.75 Controlling Application Behavior

TApplication, TScreen, and TForm are the classes that form the backbone of all applications by controlling the behavior of your project. The *TApplication* class forms the foundation of an application by providing properties and methods that encapsulate the behavior of a standard program. *TScreen* is used at runtime to keep track of forms and data modules that have been loaded as well as maintaining system-specific information such as screen resolution and available display fonts. Instances of the *TForm* class are the building blocks of your application's user interface. The windows and dialog boxes in your application are based on *TForm*.

3.2.4.5.76 Updating Actions

When the application is idle, the *OnUpdate* event occurs for every action that is linked to a control or menu item that is showing. This provides an opportunity for applications to execute centralized code for enabling and disabling, checking and unchecking, and so on. For example, the following code illustrates the *OnUpdate* event handler for an action that is "checked" when the toolbar is visible:

```
procedure TForm1.Action1Update(Sender: TObject);
begin
{ Indicate whether ToolBar1 is currently visible }
(Sender as TAction).Checked := ToolBar1.Visible;
end;
void __fastcall TForm1::Action1Update(TObject *Sender)
{
// Indicate whether ToolBar1 is currently visible
((TAction *)Sender)->Checked = ToolBar1->Visible;
}
```

Warning: Do not add time-intensive code to the *OnUpdate* event handler. This executes whenever the application is idle. If the event handler takes too much time, it will adversely affect performance of the entire application.

3.2.4.5.77 Using Action Lists

Note: The contents of this topic apply to setting up toolbars and menus for cross-platform development. For Windows development you can also use the methods described here. However, using action bands instead is simpler and offers more options. The action lists will be handled automatically by the Action Manager. See Organizing actions for toolbars and menus (see page 1992) for details.

Action lists maintain a list of actions that your application can take in response to something a user does. By using action objects, you centralize the functions performed by your application from the user interface. This lets you share common code for performing actions (for example, when a toolbar button and menu item do the same thing), as well as providing a single, centralized way to enable and disable actions depending on the state of your application.

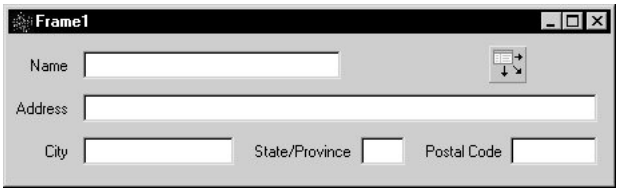
3.2.4.5.78 Using and Modifying Frames

To use a frame in an application, you must place it, directly or indirectly, on a form. You can add frames directly to forms, to other frames, or to other container objects such as panels and scroll boxes.

The Form Designer provides two ways to add a frame to an application:



- Select a frame from the **Tool palette** and drop it onto a form, another frame, or another container object. If necessary, the Form Designer asks for permission to include the frame's unit file in your project.
- Select *Frames* from the Standard category of the **Tool palette** and click on a form or another frame. A dialog appears with a list of frames that are already included in your project; select one and click OK.

When you drop a frame onto a form or other container, Delphi declares a new class that descends from the frame you selected. (Similarly, when you add a new form to a project, Delphi declares a new class that descends from *TForm*.) This means that changes made later to the original (ancestor) frame propagate to the embedded frame, but changes to the embedded frame do not propagate backward to the ancestor.

Suppose, for example, that you wanted to assemble a group of data-access components and data-aware controls for repeated use, perhaps in more than one application. One way to accomplish this would be to collect the components into a component template; but if you started to use the template and later changed your mind about the arrangement of the controls, you would have to go back and manually alter each project where the template was placed.

If, on the other hand, you put your database components into a frame, later changes would need to be made in only one place; changes to an original frame automatically propagate to its embedded descendants when your projects are recompiled. At the same time, you are free to modify any embedded frame without affecting the original frame or other embedded descendants of it. The only limitation on modifying embedded frames is that you cannot add components to them.

A frame with data-aware controls and a data source component:

In addition to simplifying maintenance, frames can help you to use resources more efficiently. For example, to use a bitmap or other graphic in an application, you might load the graphic into the Picture property of a *TImage* control. If, however, you use the same graphic repeatedly in one application, each *Image* object you place on a form will result in another copy of the graphic being added to the form's resource file. (This is true even if you set *TImage.Picture* once and save the *Image* control as a component template.) A better solution is to drop the *Image* object onto a frame, load your graphic into it, then use the frame where you want the graphic to appear. This results in smaller form files and has the added advantage of letting you change the graphic everywhere it occurs simply by modifying the *Image* on the original frame.

3.2.4.5.79 Using Menu Templates

Several predesigned menus, or menu templates, contain frequently used commands. You can use these menus in your applications without modifying them (except to write code), or you can use them as a starting point, customizing them as you would a menu you originally designed yourself. Menu templates do not contain any event handler code.

The menu templates are stored in the BIN subdirectory in a default installation and have a .dmt extension.

You can also save as a template any menu that you design using the Menu Designer. After saving a menu as a template, you can use it as you would any predesigned menu. If you decide you no longer want a particular menu template, you can delete it from the list.

To add a menu template to your application

1. Right-click the Menu Designer and choose Insert From Template. (If there are no templates, the Insert From Template option appears dimmed in the context menu.) The Insert Template dialog box opens, displaying a list of available menu templates.

2. Select the menu template you want to insert, then press Enter or choose OK. This inserts the menu into your form at the cursor's location. For example, if your cursor is on a menu item in a list, the menu template is inserted above the selected item. If your cursor is on the menu bar, the menu template is inserted to the left of the cursor.

To delete a menu template

1. Right-click the Menu Designer and choose Delete Templates. (If there are no templates, the Delete Templates option appears dimmed in the context menu.) The Delete Templates dialog box opens, displaying a list of available templates.
2. Select the menu template you want to delete, and press `Del`. Delphi deletes the template from the templates list and from your hard disk.

Creating and Managing Menus (see page 1975)

3.2.4.5.80 Using the Main Form

The first form you create and save in a project becomes, by default, the project's main form, which is the first form created at runtime. As you add forms to your projects, you might decide to designate a different form as your application's main form. Also, specifying a form as the main form is an easy way to test it at runtime, because unless you change the form creation order, the main form is the first form displayed in the running application.

To change the project main form:

1. Choose **Project** ▸ **Options** and select the Forms page.

2. In the Main Form combo box, select the form you want to use as the project's main form and choose OK.

Now if you run the application, the form you selected as the main form is displayed.

TForm

Hiding the Main Form (see page 1986)

3.2.4.5.81 Using the Menu Designer Context Menu

The Menu Designer context menu provides quick access to the most common Menu Designer commands, and to the menu template options. (For more information about menu templates, refer to Using menu templates (see page 2009).)

To display the context menu, right-click the Menu Designer window, or press *Alt+F10* when the cursor is in the Menu Designer window.

Commands on the context menu

The following table summarizes the commands on the Menu Designer context menu.

Menu Designer context menu commands

Menu command	Action
Insert	Inserts a placeholder above or to the left of the cursor.
Delete	Deletes the selected menu item (and all its sub-items, if any).
Create Submenu	Creates a placeholder at a nested level and adds an arrow to the right of the selected menu item.
Select Menu	Opens a list of menus in the current form. Double-clicking a menu name opens the designer window for the menu.
Save As Template	Opens the Save Template dialog box, where you can save a menu for future reuse.
Insert From Template	Opens the Insert Template dialog box, where you can select a template to reuse.
Delete Templates	Opens the Delete Templates dialog box, where you can choose to delete any existing templates.
Insert From Resource	Opens the Insert Menu from Resource file dialog box, where you can choose a .rc or .mnu file to open in the current form.

3.2.4.5.82 Creating a Form Instance Using a Local Variable

A safer way to create a unique instance of a *modal form* is to use a local variable in the event handler as a reference to a new instance. If a local variable is used, it does not matter whether *ResultsForm* is auto-created or not. The code in the event handler makes no reference to the global form variable. For example:

```
procedure TMainForm.Button1Click(Sender: TObject);
var
  RF:TResultForm;
begin
  RF:=TResultForm.Create(self)
  RF.ShowModal;
  RF.Free;
end;
```

```
void __fastcall TMainMForm::FirstButtonClick(TObject *Sender)
{
TResultsForm *rf = new TResultsForm(this);
rf->ShowModal();
delete rf;
}
```

Notice how the global instance of the form is never used in this version of the event handler.

Typically, applications use the global instances of forms. However, if you need a new instance of a modal form, and you use that form in a limited, discrete section of the application, such as a single function, a local instance is usually the safest and most efficient way of working with the form.

Of course, you cannot use local variables in event handlers for modeless forms because they must have global scope to ensure that the forms exist for as long as the form is in use. *Show* returns as soon as the form opens, so if you used a local variable, the local variable would go out of scope immediately.

3.2.4.5.83 Viewing the Menu

You can view your menu in the form at design time without first running your program code. (Pop-up menu components are visible in the form at design time, but the pop-up menus themselves are not. Use the Menu Designer to view a pop-up menu at design time.)

To view the menu:

1. If the form is visible, click the form, or from the View menu, choose the form whose menu you want to view.
2. If the form has more than one menu, select the menu you want to view from the form's Menu property drop-down list. The menu appears in the form exactly as it will when you run the program.

Creating and Managing Menus (see page 1975)

3.2.4.5.84 What Is an Action?

As you are developing your application, you can create a set of actions that you can use on various UI elements. You can organize them into categories that can be dropped onto a menu as a set (for example, Cut, Copy, and Paste) or one at a time (for example, **Tools** ▸ **Customize**).

An action corresponds to one or more elements of the user interface, such as menu commands or toolbar buttons. Actions serve two functions: (1) they represent properties common to the user interface elements, such as whether a control is enabled or checked, and (2) they respond when a control fires, for example, when the application user clicks a button or chooses a menu item. You can create a repertoire of actions that are available to your application through menus, through buttons, through toolbars, context menus, and so on.

Actions are associated with other components:

- **Clients:** One or more clients use the action. The client most often represents a menu item or a button (for example, *TToolButton*, *TSpeedButton*, *TMenuItem*, *TButton*, *TCheckBox, TRadioButton*, and so on). Actions also reside on ActionBand components such as TActionMainMenuBar *and* TActionToolBar. When the client receives a user command (such as a mouse click), it initiates an associated action. Typically, a client's *OnClick* event is associated with its action's *OnExecute* event.
- **Target:** The action acts on the target. The target is usually a control, such as a memo or a data control. Component writers can create actions specific to the needs of the controls they design and use, and then package those units to create more

modular applications. Not all actions use a target. For example, the standard help actions ignore the target and simply launch the help system.

A target can also be a component. For example, data controls change the target to an associated dataset.

The client influences the action—the action responds when a client fires the action. The action also influences the client—action properties dynamically update the client properties. For example, if at runtime an action is disabled (by setting its *Enabled* property to *False*), every client of that action is disabled, appearing grayed.

You can add, delete, and rearrange actions using the Action Manager or the Action List editor (displayed by double-clicking an action list object, *TActionList*). These actions are later connected to client controls. See Creating toolbars and menus (see page 1978) and, for cross-platform development, Setting up action lists (see page 2003) for details.

3.2.4.5.85 Working at the Application Level

The global variable *Application*, of type *TApplication*, is in every VCL-based application. *Application* encapsulates your application as well as providing many functions that occur in the background of the program. For instance, *Application* handles how you call a Help file from the menu of your program. Understanding how *TApplication* works is more important to a component writer than to developers of stand-alone applications, but you should set the options that *Application* handles in the **Project ▶ Options** Application page when you create a project.

In addition, *Application* receives many events that apply to the application as a whole. For example, the *OnActivate* event lets you perform actions when the application first starts up, the *OnIdle* event lets you perform background processes when the application is not busy, the *OnMessage* event lets you intercept Windows messages (on Windows only), the *OnEvent* event lets you intercept events, and so on. Although you can't use the IDE to examine the properties and events of the global *Application* variable, another component, *TApplicationEvents*, intercepts the events and lets you supply event-handlers using the IDE.

TApplication

3.2.4.5.86 Working with Frames

A frame (*TFrame*), like a form, is a container for other components. It uses the same ownership mechanism as forms for automatic instantiation and destruction of the components on it, and the same parent-child relationships for synchronization of component properties.

In some ways, however, a frame is more like a customized component than a form. Frames can be saved on the **Tool palette** for easy reuse, and they can be nested within forms, other frames, or other container objects. After a frame is created and saved, it continues to function as a unit and to inherit changes from the components (including other frames) it contains. When a frame is embedded in another frame or form, it continues to inherit changes made to the frame from which it derives.

Frames are useful to organize groups of controls that are used in multiple places in your application. For example, if you have a bitmap that is used on multiple forms, you can put it in a frame and only one copy of that bitmap is included in the resources of your application. You could also describe a set of edit fields that are intended to edit a table with a frame and use that whenever you want to enter data into the table.

3.2.4.5.87 Writing Action Components

You can also create your own predefined action classes. When you write your own action classes, you can build in the ability to execute on certain target classes of objects. Then, you can use your custom actions in the same way you use predefined action classes. That is, when the action can recognize and apply itself to a target class, you can simply assign the action to a client control, and it acts on the target with no need to write an event handler.

Component writers can use the classes in the QStdActns and DBActns units as examples for deriving their own action classes to implement behaviors specific to certain controls or components. The base classes for these specialized actions (*TEditAction, TWindowAction*, and so on) generally override *HandlesTarget*, *UpdateTarget*, and other methods to limit the target for the action to a specific class of objects. The descendant classes typically override *ExecuteTarget* to perform a specialized task. These methods are described here:

Methods overriden by base classes of specific actions

Method	Description
HandlesTarget	Called automatically when the user invokes an object (such as a tool button or menu item) that is linked to the action. The *HandlesTarget* method lets the action object indicate whether it is appropriate to execute at this time with the object specified by the *Target* parameter as a "target". See How actions find their targets (see page 1987) for details.
UpdateTarget	Called automatically when the application is idle so that actions can update themselves according to current conditions. Use in place of *OnUpdateAction*. See Updating actions (see page 2007) for details.
ExecuteTarget	Called automatically when the action fires in response to a user action in place of *OnExecute* (for example, when the user selects a menu item or presses a tool button that is linked to this action). See What happens when an action fires (see page 1984) for details.

When you write your own action classes, it is important to understand the following:

- How actions find their targets (see page 1987)
- Registering actions (see page 1996)

3.2.4.5.88 Using Windows Common Dialog Boxes

One of the commonly used dialog box components is *TOpenDialog*. This component is usually invoked by a New or Open menu item under the File option on the main menu bar of a form. The dialog box contains controls that let you select groups of files

using a wildcard character and navigate through directories.

The *TOpenDialog* component makes an Open dialog box available to your application. The purpose of this dialog box is to let a user specify a file to open. You use the *Execute* method to display the dialog box.

When the user chooses OK in the dialog box, the user's file is stored in the *TOpenDialog FileName* property, which you can then process as you want.

The following code can be placed in an *Action* and linked to the *Action* property of a *TMainMenu* subitem or be placed in the subitem's *OnClick* event:

```
if OpenDialog1.Execute then
   filename := OpenDialog1.FileName;
if(OpenDialog1->Execute()){
   filename = OpenDialog1->FileName;
};
```

This code will show the dialog box and if the user presses the OK button, it will copy the name of the file into a previously declared *AnsiString* variable named `filename`.

3.2.4.6 Exception handling

Topics

Name	Description
Unwinding Exceptions (C++) (see page 2016)	When an exception is thrown, the runtime library takes the thrown object, gets the type of the object, and looks upward in the call stack for a handler whose type matches the type of the thrown object. Once a handler is found, the RTL unwinds the stack to the point of the handler, and executes the handler. In the unwind process, the RTL calls destructors for all local objects in the stack frames between where the exception was thrown and where it is caught. If a destructor causes an exception to be raised during stack unwinding and does not handle... more (see page 2016)
Exception Handling Options (C++) (see page 2016)	The following exception handling options are available for bcc32:
Constructors In Exception Handling (C++) (see page 2017)	Class constructors can throw exceptions if they cannot successfully construct an object. If a constructor throws an exception, that object's destructor is not necessarily called. Destructors are called only for the base classes and for those objects that were fully constructed inside the classes since entering the try block. **Note:** This does not apply to VCL base classes.
Defining Protected Blocks (see page 2017)	To prepare for exceptions, you place statements that might raise them in a try block (see page 2026). If one of these statements does raise an exception, control is transferred to an exception handler that handles that type of exception, then leaves the block. The exception handler is said to *catch* the exception and specifies the actions to take. By using try blocks and exception handlers, you can move error checking and error handling out of the main flow of your algorithms, resulting in simpler, more readable code. You start a protected block using the keyword **try**. The exception handler must... more (see page 2017)
Exception Handling (see page 2018)	Exceptions are exceptional conditions that require special handling. They include errors that occur at runtime, such as divide by zero, and the exhaustion of free store. Exception handling provides a standard way of dealing with errors, discovering both anticipated and unanticipated problems, and enables developers to recognize, track down, and fix bugs. When an error occurs, the program raises an exception, meaning it creates an exception object and rolls back the stack to the first point it finds where you have code to handle the exception. The exception object usually contains information about what happened. This allows another part of... more (see page 2018)
Exception-handling Statements (see page 2018)	The exception handling block starts with the **except** keyword and ends with the keyword **end**. These two keywords are actually part of the same statement as the try block. That is, both the try block and the exception handling block are considered part of a single **try...except** statement. Inside the exception handling block, you include one or more exception handlers. An exception handler is a statement of the form
Throwing An Exception (C++) (see page 2019)	To raise an exception in C++, use the **throw** keyword. Objects in C++ can be thrown by value, or pointer:

Raising an Exception (see page 2020)	To indicate a disruptive error condition, you can raise an exception by constructing an instance of an exception object that describes the error condition and calling the reserved word **raise**. To raise an exception, call the reserved word **raise**, followed by an instance of an exception object. This establishes the exception as coming from a particular address. When an exception handler actually handles the exception, it finishes by destroying the exception instance, so you never need to do that yourself. For example, given the following declaration,
Reraising Exceptions (see page 2020)	Sometimes when you handle an exception locally, you want to augment the handling in the enclosing block, rather than replace it. Of course, when your local handler finishes its handling, it destroys the exception instance, so the enclosing block's handler never gets to act. You can, however, prevent the handler from destroying the exception, giving the enclosing handler a chance to respond. You do this by using the raise command with no arguments. This is called reraising or rethrowing the exception. The following example illustrates this technique:
Smart Pointers (C++) (see page 2021)	If you have local variables that are pointers to objects and an exception is thrown, these pointers are not automatically deleted. This is because there is no good way for the compiler to distinguish between a pointer to data that was allocated for this function only and any other pointer. The class that you can use to ensure that objects allocated for local use are destroyed in the even of an exception is `auto_ptr`. There is a special case in which memory is freed for a pointer allocated in a function:
Scope of Exception Handlers (see page 2021)	You do not need to provide handlers for every kind of exception in every block. You only need handlers for exceptions that you want to handle specially within a particular block. If a block does not handle a particular exception, execution leaves that block and returns to the block that contains it (or returns to the code that called the block), with the exception still raised. This process repeats with increasingly broad scope until either execution reaches the outermost scope of the application or a block at some level handles the exception. Thus, you can nest your exception handling code.... more (see page 2021)
Silent Exceptions (see page 2022)	VCL applications handle most exceptions that your code doesn't specifically handle by displaying a message box that shows the message string from the exception object. You can also define "silent" exceptions that do not, by default, cause the application to show the error message. Silent exceptions are useful when you don't intend to report an exception to the user, but you want to abort an operation. Aborting an operation is similar to using the *Break* or *Exit* procedures to break out of a block, but can break out of several nested levels of blocks. Silent exceptions all descend from the... more (see page 2022)
Writing a finally Block (C++) (see page 2023)	`bcc32` includes extensions to the C++ language that let it use finally blocks as well. Like exception handlers, a finally block must appear directly after the **try** block, but it is introduced by the__**finally** keyword instead of **catch**.
Writing a Finally Block (Delphi) (see page 2024)	Finally blocks are introduced by the keyword **finally**. They are part of a **try..finally** statement, which has the following form:
Writing Exception Handlers (see page 2024)	The exception handling block appears immediately after the try block. This block incudes one or more exception handlers. An exception handler provides a specific response to a specific kind of exception. Handling an exception clears the error condition and destroys the exception object, which allows the application to continue execution. You typically define exception handlers to allow your applications to recover from errors and continue running. Types of exceptions you might handle include attempts to open files that don't exist, writing to full disks, or calculations that exceed legal bounds. Some of these, such as "File not found," are... more (see page 2024)
Writing finally Blocks (see page 2025)	An exception handler is code that handles a specific exception or exceptions that occur within a protected block of code. However, there are times when you do not need to handle the exception, but you do have code that you want to execute after the protected block, even if an exception occurs. Typically, such code handles cleanup issues, such as freeing resources that were allocated before the protected block. By using finally blocks, you can ensure that if your application allocates resources, it also releases them, even if an exception occurs. Thus, if your application allocates memory, you can make... more (see page 2025)
Writing the Try Block (see page 2026)	The first part of a protected block is the try block. The try block contains code that can potentially raise an exception. The exception can be raised either directly in the try block, or by code that is called by statements in the try block. That is, if code in a try block calls a routine that doesn't define its own exception handler, then any exceptions raised inside that routine cause execution to pass to the exception-handler associated with the try block. Keep in mind that exceptions don't come just from your code. A call to an RTL routine or... more (see page 2026)

Handling Classes of Exceptions (see page 2027)	Exceptions are always represented by classes. As such, you usually work with a hierarchy of exception classes. For example, VCL defines the *ERangeError* exception as a descendant of *EIntError*. When you provide an exception handler for a base exception class, it catches not only direct instances of that class, but instances of any of its descendants as well. For example, the following exception handler handles all integer math exceptions, including *ERangeError*, *EDivByZero*, and *EIntOverflow*:
VCL Exception Classes (see page 2028)	VCL includes a large set of built-in exception classes for automatically handling divide-by-zero errors, file I/O errors, invalid typecasts, and many other exception conditions. All VCL exception classes descend from one root object called Exception. *Exception* provides a consistent interface for applications to handle exceptions. It provides the string for the message that VCL exceptions display by default. The following table lists a selection of the exception classes defined in VCL: ***Selected exception classes***
Default Exception Handling in VCL (see page 2029)	If your application code does not catch and handle the exceptions that are raised, the exceptions are ultimately caught and handled by the *HandleException* method of the global *Application* object. For all exceptions but *EAbort*, *HandleException* calls the *OnException* event handler, if one exists. If there is no *OnException* event handler (and the exception is not *EAbort*), *HandleException* displays a message box with the error message associated with the exception. There are certain circumstances where *HandleException* does not get called. Exceptions that occur before or after the execution of the application's Run method are not caught and handled... more (see page 2029)
Defining Your Own VCL Exceptions (see page 2029)	Because VCL exceptions are classes, defining a new kind of exception is as simple as declaring a new class type. Although you can raise any object instance as an exception, the standard VCL exception handlers handle only exceptions that descend from *Exception*. New exception classes should be derived from *Exception* or one of the other standard exceptions. That way, if you raise your new exception in a block of code that isn't protected by an exception handler specific to that exception, one of the standard handlers will handle it instead. For example, consider the following declaration:
Handling Exceptions in VCL Applications (see page 2030)	If you use VCL components or the VCL runtime library in your applications, you need to understand the VCL exception handling mechanism. Exceptions are built into many VCL classes and routines and they are thrown automatically when something unexpected occurs. Typically, these exceptions indicate programming errors that would otherwise generate a runtime error. A limited number of these classes is described in VCL Exception Classes (see page 2028). The mechanics of handling component exceptions are no different than handling any other type of exception. If you do not handle the exception, VCL handles it in a default manner (see page 2029). Typically, a message... more (see page 2030)

3.2.4.6.1 Unwinding Exceptions (C++)

When an exception is thrown, the runtime library takes the thrown object, gets the type of the object, and looks upward in the call stack for a handler whose type matches the type of the thrown object. Once a handler is found, the RTL unwinds the stack to the point of the handler, and executes the handler.

In the unwind process, the RTL calls destructors for all local objects in the stack frames between where the exception was thrown and where it is caught. If a destructor causes an exception to be raised during stack unwinding and does not handle it, terminate is called. Destructors are called by default, but you can switch off the default by using the -xd compiler option.

Note: During the unwind process, the RTL does not call destructors for objects that are allocated on the heap rather than the stack. This is why, for example, VCL applications use finally

blocks to ensure that VCL objects, which are always allocated on the heap, are properly freed. There is one exception to this rule, which is the use of safe pointers.

3.2.4.6.2 Exception Handling Options (C++)

The following exception handling options are available for bcc32:

-x	Enables C++ exception handling. Enabled by default.
-xd	Enables destructor cleanup. Calls destructors for all automatically declared objects between the scope of the **catch** and **throw** statements when an exception is thrown. Enabled by default.
-xp	Enables the program to use the `__ThrowFileName` global to obtain the file where the exception occurred and the `__ThrowLineNumber` global to access the line number from where the C++ exception was thrown. Disabled by default.

3.2.4.6.3 Constructors In Exception Handling (C++)

Class constructors can throw exceptions if they cannot successfully construct an object. If a constructor throws an exception, that object's destructor is not necessarily called. Destructors are called only for the base classes and for those objects that were fully constructed inside the classes since entering the try block.

Note: This does not apply to VCL base classes.

Exception Handling Options (see page 2016)

Unwinding Exceptions (C++) (see page 2016)

3.2.4.6.4 Defining Protected Blocks

To prepare for exceptions, you place statements that might raise them in a try block (see page 2026). If one of these statements does raise an exception, control is transferred to an exception handler that handles that type of exception, then leaves the block. The exception handler is said to *catch* the exception and specifies the actions to take. By using try blocks and exception handlers, you can move error checking and error handling out of the main flow of your algorithms, resulting in simpler, more readable code.

You start a protected block using the keyword **try**. The exception handler must immediately follow the try block. It is introduced by the keyword **except**, and signals the end of the try block. This syntax is illustrated in the following code. If the *SetFieldValue* method fails and raises an *EIntegerRange* exception, execution jumps to the exception-handling part, which displays an error message. Execution resumes outside the block.

```
try
  SetFieldValue(dataField, userValue);
except
  on E: EIntegerRange do
    ShowMessage(Format('Expected value between %d and %d, but got %d',
                       E.Min, E.Max, E.Value));
end;
  .  { execution resumes here, outside the protected block }
  .
  .
try
{
SetFieldValue(dataField, userValue);
}
catch (EIntegerRange &E)
{
  ShowMessage(Format("Expected value between %d and %d, but got %d\n",
              E.Min, E.Max, E.Value));
}
// execution resumes here, outside the protected block
```

You must have an *exception handling block* (described in Writing Exception Handlers (see page 2024)) or a *finally block*

(described in Writing Finally Blocks (see page 2025)) immediately after the try block. An exception handling block should include a handler for each exception that the statements in the try block can generate.

See Also

Writing Exception Handlers (see page 2024)

3.2.4.6.5 Exception Handling

Exceptions are exceptional conditions that require special handling. They include errors that occur at runtime, such as divide by zero, and the exhaustion of free store. Exception handling provides a standard way of dealing with errors, discovering both anticipated and unanticipated problems, and enables developers to recognize, track down, and fix bugs.

When an error occurs, the program raises an exception, meaning it creates an exception object and rolls back the stack to the first point it finds where you have code to handle the exception. The exception object usually contains information about what happened. This allows another part of the program to diagnose the cause of the exception.

To make your applications robust, your code needs to recognize exceptions when they occur and respond to them. If you don't specify a response, the application presents a message box describing the error. Your job, then, is to recognize places where errors might happen, and define responses, particularly in areas where errors could cause the loss of data or system resources.

When you create a response to an exception, you do so on blocks of code. When you have a series of statements that all require the same kind of response to errors, you can group them into a block and define error responses that apply to the whole block.

Blocks with specific responses to exceptions are called protected blocks because they can guard against errors that might otherwise either terminate the application or damage data.

See Defining Protected Blocks (see page 2017) for details on how to create and handle exceptions.

For information on using exceptions with the routines and classes in VCL, see Handling Exceptions in VCL Applications (see page 2030).

See Also

Creating Applications (see page 1883)

3.2.4.6.6 Exception-handling Statements

The exception handling block starts with the **except** keyword and ends with the keyword **end**. These two keywords are actually part of the same statement as the try block. That is, both the try block and the exception handling block are considered part of a single **try...except** statement.

Inside the exception handling block, you include one or more exception handlers. An exception handler is a statement of the form

```
on <type of exception> do <statement>;
```

For example, the following exception handling block includes multiple exception handlers for different exceptions that can arise from an arithmetic computation:

```
try
{ calculation statements }
except
  on EZeroDivide do Value := MAXINT;
  on EIntOverflow do Value := 0;
  on EIntUnderflow do Value := 0;
end;
```

Much of the time, as in the previous example, the exception handler doesn't need any information about an exception other than its type, so the statements following **on..do** are specific only to the type of exception. In some cases, however, you might need

some of the information contained in the exception instance.

To read specific information about an exception instance in an exception handler, you use a special variation of **on..do** that gives you access to the exception instance. The special form requires that you provide a temporary variable to hold the instance. For example:

```
on E: EIntegerRange do
  ShowMessage(Format('Expected value between %d and %d', E.Min, E.Max));
```

The temporary variable (E in this example) is of the type specified after the colon (*EIntegerRange* in this example). You can use the as operator to typecast the exception into a more specific type if needed.

Warning: Never destroy the temporary exception object. Handling an exception automatically destroys the exception object. If you destroy the object yourself, the application attempts to destroy the object again, generating an access violation.

You can provide a single default exception handler to handle any exceptions for which you haven't provided specific handlers. To do that, add an else part to the exception-handling block:

```
try
{ statements }
except
  on ESomething do
    { specific exception-handling code };
  else
    { default exception-handling code };
end;
```

Adding default exception handling to a block guarantees that the block handles every exception in some way, thereby overriding all handling from any containing block.

Warning: It is not advisable to use this all-encompassing default exception handler. The else clause handles all exceptions, including those you know nothing about. In general, your code should handle only exceptions you actually know how to handle. If you want to handle cleanup and leave the exception handling to code that has more information about the exception and how to handle it, then you can do so using a finally block. For details about finally blocks, see Writing Finally Blocks (see page 2025).

See Also

Writing a Finally Block (see page 2024)

Handling Classes of Exceptions (see page 2027)

Scope of Exception Handlers (see page 2021)

Reraising Exceptions (see page 2020)

3.2.4.6.7 Throwing An Exception (C++)

To raise an exception in C++, use the **throw** keyword. Objects in C++ can be thrown by value, or pointer:

```
// throw an object, to be caught by value or reference
throw EIntegerRange(0, 10, userValue);
// throw an object to be caught by pointer
throw new EIntegerRange(0, 10, userValue);
```

Tip: Throw exceptions by value and catch exceptions by reference to prevent memory leaks. If you catch an exception by pointer, you may not be able to delete the exception object.

Note: To throw an exception by value, it must have a public copy constructor and public destructor.

In addition, the throw statement can throw other types as well. Although it is not recommended, C++ lets you throw primitive types, such as integers or pointers:

```
throw 1;       // throw an int
throw "catastrophic error";           // throw a char *
```

In most cases, you want to throw exception objects because they can provide a more complete description of an error.

3.2.4.6.8 Raising an Exception

To indicate a disruptive error condition, you can raise an exception by constructing an instance of an exception object that describes the error condition and calling the reserved word **raise**.

To raise an exception, call the reserved word **raise**, followed by an instance of an exception object. This establishes the exception as coming from a particular address. When an exception handler actually handles the exception, it finishes by destroying the exception instance, so you never need to do that yourself.

For example, given the following declaration,

```
type
  EPasswordInvalid = class(Exception);
```

you can raise a "password invalid" exception at any time by calling raise with an instance of *EPasswordInvalid*, like this:

```
if Password <> CorrectPassword then
  raise EPasswordInvalid.Create('Incorrect password entered');
```

Raising an exception sets the *ErrorAddr* variable in the System unit to the address where the application raised the exception. You can refer to *ErrorAddr* in your exception handlers, for example, to notify the user where the error occurred. You can also specify a value in the raise clause that appears in *ErrorAddr* when an exception occurs.

Warning: Do not assign a value to *ErrorAddr* yourself. It is intended as read-only.

To specify an error address for an exception, add the reserved word *at* after the exception instance, followed by an address expression such as an identifier.

Exception-handling Statements (see page 2018)

Writing a Finally Block (see page 2024)

Reraising Exceptions (see page 2020)

3.2.4.6.9 Reraising Exceptions

Sometimes when you handle an exception locally, you want to augment the handling in the enclosing block, rather than replace it. Of course, when your local handler finishes its handling, it destroys the exception instance, so the enclosing block's handler never gets to act. You can, however, prevent the handler from destroying the exception, giving the enclosing handler a chance to respond. You do this by using the raise command with no arguments. This is called reraising or rethrowing the exception. The following example illustrates this technique:

```
try
{ statements }
  try
{ special statements }
  except
    on ESomething do
    begin
{ handling for only the special statements }
      raise;{ reraise the exception }
    end;
  end;
except
  on ESomething do ...;{ handling you want in all cases }
```

```
end;
try
{
  // statements
  try
  {
    // special statements
  }
  catch (const ESomething &E)
  {
    // handling for only the special statements;
  }
}
catch (const ESomething &E)
{
  // handling you want in all cases
}
```

If code in the *statements* part raises an *ESomething* exception, only the handler in the outer exception-handling block executes. However, if code in the *special statements* part raises *ESomething*, the handling in the inner exception-handling block executes, followed by the more general handling in the outer exception-handling block. By reraising exceptions, you can easily provide special handling for exceptions in special cases without losing (or duplicating) the existing handlers.

If the handler wants to throw a different exception, it can use the raise or throw statement in the normal way, as described in Raising an Exception (see page 2020).

See Also

Exception-handling Statements (see page 2018)

Handling Classes of Exceptions (see page 2027)

Scope of Exception Handlers (see page 2021)

3.2.4.6.10 Smart Pointers (C++)

If you have local variables that are pointers to objects and an exception is thrown, these pointers are not automatically deleted. This is because there is no good way for the compiler to distinguish between a pointer to data that was allocated for this function only and any other pointer. The class that you can use to ensure that objects allocated for local use are destroyed in the even of an exception is `auto_ptr`. There is a special case in which memory is freed for a pointer allocated in a function:

```
auto_ptr< TMyObject > pMyObject( new TMyObject );
```

In this example, if the constructor for `TMyObject` throws an exception, then the pointer to the object allocated for TMYObject will be deleted by the RTL when it unwinds the exception. This is the only time that the compiler automatically deletes a pointer value for you.

3.2.4.6.11 Scope of Exception Handlers

You do not need to provide handlers for every kind of exception in every block. You only need handlers for exceptions that you want to handle specially within a particular block.

If a block does not handle a particular exception, execution leaves that block and returns to the block that contains it (or returns to the code that called the block), with the exception still raised. This process repeats with increasingly broad scope until either execution reaches the outermost scope of the application or a block at some level handles the exception.

Thus, you can nest your exception handling code. That is, you can use nested blocks to define local handling for specific exceptions that overrides the handling in the surrounding block. For example:

```
try
```

```
{ statements }
  try
{ special statements }
  except
    on ESomething do
    begin
{ handling for only the special statements }
    end;
  end;
  { more statements }
except
  on ESomething do
  begin
    {handling for statements and more statements, but not special statements}
  end;
end;
try
{
  // statements
  try
  {
    // special statements
  }
  catch (const ESomething &E)
  {
    // handling for only the special statements;
  }
  // more statements
}
catch (const ESomething &E)
{
  // handling for statements and more statements, but not special statements
}
```

Note: This type of nesting is not limited to exception-handling blocks. You can also use it with finally blocks (described in Writing Finally Blocks (see page 2025)) or a mix of exception-handling and finally blocks.

See Also

Exception-handling Statements (see page 2018)

Handling Classes of Exceptions (see page 2027)

Reraising Exceptions (see page 2020)

3.2.4.6.12 Silent Exceptions

VCL applications handle most exceptions that your code doesn't specifically handle by displaying a message box that shows the message string from the exception object. You can also define "silent" exceptions that do not, by default, cause the application to show the error message.

Silent exceptions are useful when you don't intend to report an exception to the user, but you want to abort an operation. Aborting an operation is similar to using the *Break* or *Exit* procedures to break out of a block, but can break out of several nested levels of blocks.

Silent exceptions all descend from the standard exception type *EAbort*. The default exception handler for VCL applications displays the error-message dialog box for all exceptions that reach it except those descended from *EAbort*.

Note: For console applications, an error-message dialog is displayed on any unhandled *EAbort* exceptions.

There is a shortcut for raising silent exceptions. Instead of manually constructing the object, you can call the *Abort* procedure. *Abort* automatically raises an *EAbort* exception, which breaks out of the current operation without displaying an error message.

Note: There is a distinction between *Abort* and *abort*. *abort* kills the application.

The following code shows a simple example of aborting an operation. On a form containing an empty list box and a button, attach the following code to the button's *OnClick* event:

```
procedure TForm1.Button1Click(Sender: TObject);
var
I, J: Integer;
begin
  for I := 1 to 10 do{ loop ten times }
    for J := 1 to 10 do {loop ten times }
    begin
      ListBox1.Items.Add(IntToStr(I) + IntToStr(J));
      if I = 7 then Abort;{ abort after the 7th iteration of outer loop}
    end;
end;
void __fastcall TForm1::Button1Click(TObject* Sender)
{
  for (int i = 1; i <= 10; i++) // loop ten times
    for (int j = 1; j <= 10; j++) // loop ten times
    {
      ListBox1->Items->Add(IntToStr(i) + IntToStr(j));
      if (i == 7)
        Abort(); // abort after 7th iteration of outer loop
    }
}
```

Note that in this example, *Abort* causes the flow of execution to break out of both the inner and outer loops, not just the inner loop.

Defining Your Own VCL Exceptions (see page 2029)

3.2.4.6.13 Writing a finally Block (C++)

bcc32 includes extensions to the C++ language that let it use finally blocks as well. Like exception handlers, a finally block must appear directly after the **try** block, but it is introduced by the__**finally** keyword instead of **catch**.

```
try
{
  // statements that may raise an exception
}
__finally
{
    // statements that are called even if there is an exception in the try block
}
```

The application always executes any statements in the finally part, even if an exception occurs in the try block. When any code in the **try** block (or any routine called by code in the **try** block) raises an exception, execution halts at that point. Once an exception handler is found, execution jumps to the finally part. After the **finally** part executes, the exception handler is called. If no exception occurs, the code in the **finally** block executes in the normal order, after all the statements in the **try** block.

The following code illustrates an event handler that uses a finally block so that when it allocates memory and generates an error, it still frees the allocated memory:

```
void __fastcall TForm1::Button1Click(TObject* Sender)
{
  int ADividend = 0;
  void *ptr = malloc(1024); // allocate 1K of memory;
```

```
  try
    int AnInteger = 10/ADividend; // this generates an exception
  __finally
    free(ptr); // this gets called anyway, despite the exception
}
```

The statements in the finally block do not depend on an exception occurring. If no statement in the **try** part raises an exception, execution continues through the finally block.

Note: Traditional C++ code does not include support for finally

block. Instead, it tends to use destructors to handle the freeing of resources. However, when working with VCL, which is written in Delphi, **finally** blocks are an important tool because of the way VCL objects must be allocated on the heap.

Tip: You can also use `std::auto_ptr` to ensure that allocated objects are deleted.

3.2.4.6.14 Writing a Finally Block (Delphi)

Finally blocks are introduced by the keyword **finally**. They are part of a **try..finally** statement, which has the following form:

```
try
{ statements that may raise an exception}
finally
{ statements that are called even if there is an exception in the try block}
end;
```

In a **try..finally** statement, the application always executes any statements in the finally part, even if an exception occurs in the try block. When any code in the try block (or any routine called by code in the try block) raises an exception, execution halts at that point. Once an exception handler is found, execution jumps to the finally part, which is called the cleanup code. After the finally part executes, the exception handler is called. If no exception occurs, the cleanup code is executed in the normal order, after all the statements in the try block.

The following code illustrates an event handler that uses a finally block so that when it allocates memory and generates an error, it still frees the allocated memory:

```
procedure TForm1.Button1Click(Sender: TObject);
var
APointer: Pointer;
AnInteger, ADividend: Integer;
begin
  ADividend := 0;
  GetMem(APointer, 1024);{ allocate 1K of memory }
  try
    AnInteger := 10 div ADividend;{ this generates an exception }
  finally
    FreeMem(APointer, 1024);{ execution resumes here, despite the exception }
  end;
end;
```

The statements in the finally block do not depend on an exception occurring. If no statement in the try part raises an exception, execution continues through the finally block.

See Also

Raising an Exception (see page 2020)

Exception-handling Statements (see page 2018)

3.2.4.6.15 Writing Exception Handlers

The exception handling block appears immediately after the try block. This block incudes one or more exception handlers. An exception handler provides a specific response to a specific kind of exception. Handling an exception clears the error condition

and destroys the exception object, which allows the application to continue execution. You typically define exception handlers to allow your applications to recover from errors and continue running. Types of exceptions you might handle include attempts to open files that don't exist, writing to full disks, or calculations that exceed legal bounds. Some of these, such as "File not found," are easy to correct and retry, while others, such as running out of memory, can be more difficult for the application or the user to correct.

The application executes the statements in and exception handler only if an exception occurs during execution of the statements in the preceding try block. When a statement in the try block raises an exception, execution immediately jumps to the exception handler, where it steps through the specified exception-handling statements, until it finds a handler that applies to the current exception.

Once the application locates an exception handler that handles the exception, it executes the statement, then automatically destroys the exception object. Execution continues at the end of the current block.

The following topics provide details on writing exception handlers:

- Exception-handling Statements (see page 2018)
- Handling Classes of Exceptions (see page 2027)
- Scope of Exception Handlers (see page 2021)
- Reraising Exceptions (see page 2020)

See Also

Writing the Try Block (see page 2026)

Writing Finally Blocks (see page 2025)

3.2.4.6.16 Writing finally Blocks

An exception handler is code that handles a specific exception or exceptions that occur within a protected block of code. However, there are times when you do not need to handle the exception, but you do have code that you want to execute after the protected block, even if an exception occurs. Typically, such code handles cleanup issues, such as freeing resources that were allocated before the protected block.

By using finally blocks, you can ensure that if your application allocates resources, it also releases them, even if an exception occurs. Thus, if your application allocates memory, you can make sure it eventually releases the memory, too. If it opens a file, you can make sure it closes the file later. Under normal circumstances, you can ensure that an application frees allocated resources by including code for both allocating and freeing. When exceptions occur, however, you need to ensure that the application still executes the resource-freeing code.

Some common resources that you should always be sure to release are:

- Files
- Memory
- Windows resources or widget library resources (Qt objects)
- Objects (instances of classes in your application)

The following event handler illustrates how an exception can prevent an application from freeing memory that it allocates:

```
procedure TForm1.Button1Click(Sender: TObject);
var
APointer: Pointer;
AnInteger, ADividend: Integer;
begin
  ADividend := 0;
  GetMem(APointer, 1024);{ allocate 1K of memory }
  AnInteger := 10 div ADividend;{ this generates an exception }
  FreeMem(APointer, 1024);{ this never gets called because of the exception}
```

```
end;
void __fastcall TForm1::Button1Click(TObject* Sender)
{
  int ADividend = 0;
  void *ptr = malloc(1024); // allocate 1K of memory;
  int AnInteger = 10/ADividend; // this generates an exception
  free(ptr); // this never gets called because of the exception
}
```

Although most errors are not that obvious, the example illustrates an important point: When an exception occurs, execution jumps out of the block, so the statement that frees the memory never gets called.

To ensure that the memory is freed, you can use a try block with a finally block.

For details on writing finally blocks, see Writing a Finally Block (see page 2024).

See Also

Writing Exception Handlers (see page 2024)

Writing the Try Block (see page 2026)

3.2.4.6.17 Writing the Try Block

The first part of a protected block is the try block. The try block contains code that can potentially raise an exception. The exception can be raised either directly in the try block, or by code that is called by statements in the try block. That is, if code in a try block calls a routine that doesn't define its own exception handler, then any exceptions raised inside that routine cause execution to pass to the exception-handler associated with the try block. Keep in mind that exceptions don't come just from your code. A call to an RTL routine or another component in your application can also raise an exception.

The following example demonstrates catching an exception thrown from a *TFileStream* object.

```
procedure TForm1.Button1Click(Sender: TObject);
var
  fileStream: TFileStream;
begin
     try
        (* Attempt to open a non-existant file *)
        fileStream := TFileStream.Create('NOT_THERE.FILE', fmOpenRead);
                                (* Process the file contents... *)
        fileStream.Free;
     except
        on EFOpenError do ShowMessage('EFOpenError Raised');
     else
        ShowMessage('Exception Raised');
     end;
end;
void __fastcall TForm1::Button1Click(TObject *Sender)
{
   TFileStream *fileStream;
      try {
// Attempt to open a non-existent file
         fileStream = new TFileStream("NOT_THERE.FILE", fmOpenRead);
// Process the file contents...
         delete fileStream;
      }
      catch(EFOpenError &e) {
         ShowMessage("EFOpenError Raised");
      }
      catch(...) {
         ShowMessage("Exception Raised");
      }
}
```

Using a try block makes your code easier to read. Instead of sprinkling error-handling code throughout your program, you isolate it in exception handlers so that the flow of your algorithms is more obvious.

This is especially true when performing complex calculations involving hundreds of steps, any one of which could fail if one of dozens of inputs were invalid. By using exceptions, you can spell out the normal expression of your algorithm, then provide for those exceptional cases when it doesn't apply. Without exceptions, you have to test every time to make sure you can proceed with each step in the calculation.

For details on raising exceptions from the code in your try block, see Raising an Exception (see page 2020).

See Also

Writing Exception Handlers (see page 2024)

Writing Finally Blocks (see page 2025)

3.2.4.6.18 Handling Classes of Exceptions

Exceptions are always represented by classes. As such, you usually work with a hierarchy of exception classes. For example, VCL defines the *ERangeError* exception as a descendant of *EIntError*.

When you provide an exception handler for a base exception class, it catches not only direct instances of that class, but instances of any of its descendants as well. For example, the following exception handler handles all integer math exceptions, including *ERangeError*, *EDivByZero*, and *EIntOverflow*:

```
try
{ statements that perform integer math operations }
except
  on EIntError do { special handling for integer math errors };
end;
```

```
try
{
  // statements that perform integer math operations
}
catch (EIntError &E)
{
  // special handling for integer math errors
}
```

You can combine error handlers for the base class with specific handlers for more specific (derived) exceptions. You do this by placing the **catch** statements in the order that you want them to be searched when an exception is thrown. For example, this block provides special handling for range errors, and other handling for all other integer math errors:

```
try
{ statements performing integer math }
except
  on ERangeError do { out-of-range handling };
  on EIntError do { handling for other integer math errors };
end;
```

```
try
{
  // statements performing integer math
}
catch (const ERangeError &rangeErr)
{
  // out-of-range handling
}
catch (const EIntError &intErr)
{
  // handling for other integer math errors
}
```

Note that if the handler for *EIntError* came before the handler for *ERangeError*, execution would never reach the specific handler

for *ERangeError*.

Scope of Exception Handlers (see page 2021)

Reraising Exceptions (see page 2020)

3.2.4.6.19 VCL Exception Classes

VCL includes a large set of built-in exception classes for automatically handling divide-by-zero errors, file I/O errors, invalid typecasts, and many other exception conditions. All VCL exception classes descend from one root object called Exception. *Exception* provides a consistent interface for applications to handle exceptions. It provides the string for the message that VCL exceptions display by default.

The following table lists a selection of the exception classes defined in VCL:

Selected exception classes

Exception class	Description
EAbort	Stops a sequence of events without displaying an error message dialog box.
EAccessViolation	Checks for invalid memory access errors.
EBitsError	Prevents invalid attempts to access a Boolean array.
EComponentError	Signals an invalid attempt to register or rename a component.
EConvertError	Indicates string or object conversion errors.
EDatabaseError	Specifies a database access error.
EDBEditError	Catches data incompatible with a specified mask.
EDivByZero	Catches integer divide-by-zero errors.
EExternalException	Signifies an unrecognized exception code.
EInOutError	Represents a file I/O error.
EIntOverflow	Specifies integer calculations whose results are too large for the allocated register.
EInvalidCast	Checks for illegal typecasting.
EInvalidGraphic	Indicates an attempt to work with an unrecognized graphic file format.
EInvalidOperation	Occurs when invalid operations are attempted on a component.
EInvalidPointer	Results from invalid pointer operations.
EMenuError	Involves a problem with menu item.
EOleCtrlError	Detects problems with linking to ActiveX controls.
EOleError	Specifies OLE automation errors.
EPrinterError	Signals a printing error.
EPropertyError	Occurs on unsuccessful attempts to set the value of a property.
ERangeError	Indicates an integer value that is too large for the declared type to which it is assigned.
ERegistryException	Specifies registry errors.
EZeroDivide	Catches floating-point divide-by-zero errors.

There are other times when you will need to create your own exception classes to handle unique situations. You can declare a

new exception class by making it a descendant of type *Exception* and creating as many constructors as you need (or copy the constructors from an existing class in the SysUtils unit).

Silent Exceptions (see page 2022)

Defining Your Own VCL Exceptions (see page 2029)

3.2.4.6.20 Default Exception Handling in VCL

If your application code does not catch and handle the exceptions that are raised, the exceptions are ultimately caught and handled by the *HandleException* method of the global *Application* object. For all exceptions but *EAbort*, *HandleException* calls the *OnException* event handler, if one exists. If there is no *OnException* event handler (and the exception is not *EAbort*), *HandleException* displays a message box with the error message associated with the exception.

There are certain circumstances where *HandleException* does not get called. Exceptions that occur before or after the execution of the application's Run method are not caught and handled by *HandleException*. When you write a callback function or a library (.dll or shared object) with functions that can be called by an external application, exceptions can escape the *Application* object. To prevent exceptions from escaping in this manner, you can insert your own call to the *HandleException* method:

```
try
{ special statements }
except
  on Exception do
  begin
    Application.HandleException(Self);{ call HandleException }
  end;
end;
try
{
  // special statements
}
catch (Exception &E)
{
  Application->HandleException(this);
}
```

Warning: Do not call *HandleException* from a thread's exception handling code.

VCL Exception Classes (see page 2028)

Silent Exceptions (see page 2022)

Defining Your Own VCL Exceptions (see page 2029)

3.2.4.6.21 Defining Your Own VCL Exceptions

Because VCL exceptions are classes, defining a new kind of exception is as simple as declaring a new class type. Although you can raise any object instance as an exception, the standard VCL exception handlers handle only exceptions that descend from *Exception*.

New exception classes should be derived from *Exception* or one of the other standard exceptions. That way, if you raise your new exception in a block of code that isn't protected by an exception handler specific to that exception, one of the standard handlers will handle it instead.

For example, consider the following declaration:

```
type
  EMyException = class(Exception);
class EMyException : public Exception
{
};
```

If you raise *EMyException* but don't provide a specific handler for it, a handler for *Exception* (or a default exception handler) will still handle it. Because the standard handling for *Exception* displays the name of the exception raised, you can see that it is your new exception that is raised.

VCL Exception Classes (see page 2028)

Default Exception Handling in VCL (see page 2029)

Silent Exceptions (see page 2022)

3.2.4.6.22 Handling Exceptions in VCL Applications

If you use VCL components or the VCL runtime library in your applications, you need to understand the VCL exception handling mechanism. Exceptions are built into many VCL classes and routines and they are thrown automatically when something unexpected occurs. Typically, these exceptions indicate programming errors that would otherwise generate a runtime error. A limited number of these classes is described in VCL Exception Classes (see page 2028).

The mechanics of handling component exceptions are no different than handling any other type of exception.

If you do not handle the exception, VCL handles it in a default manner (see page 2029). Typically, a message displays describing the type of error that occurred. While debugging your application, you can look up the exception class in online Help. The information provided will often help you to determine where the error occurred and its cause.

Certain classes of exceptions do not display an error message when caught by the default handlers. These are described in Silent Exceptions (see page 2022).

A common source of errors in components is range errors in indexed properties. For example, if a list box has three items in its list (0..2) and your application attempts to access item number 3, the list box raises a "List index out of bounds" exception.

The following event handler contains an exception handler to notify the user of invalid index access in a list box:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  ListBox1.Items.Add('a string');{ add a string to list box }
  ListBox1.Items.Add('another string');{ add another string... }
  ListBox1.Items.Add('still another string');{ ...and a third string }
  try
    Caption :=

ListBox1.Items[3]

;{ set form caption to fourth string }
  except
    on EStringListError do
      ShowMessage('List box contains fewer than four strings');
  end;
end;
void __fastcall TForm1::Button1Click(TObject* Sender)
{
  ListBox1->Items->Add("a string"); // add a string to list box
  ListBox1->Items->Add("another string"); // add another string ...
  ListBox1->Items->Add("still another string"); // ... and a third string
  try
    Caption =
ListBox1->Items->Strings[3]
```

```
; // set form caption to 4th string
  catch (EStringListError &E)
    ShowMessage("List box contains fewer than four strings");
}
```

If you click the button once, the list box has only three strings, so accessing the fourth string raises an exception. Clicking a second time adds more strings to the list, so it no longer causes the exception.

In addition to handling the exceptions that VCL raises, you can define and raise your own VCL-based exception classes. This is discussed in Defining Your Own VCL Exceptions (see page 2029).

Defining Protected Blocks (see page 2017)

3.2.4.7 Types of controls

Topics

Name	Description
Value List Editors (VCL Only) (see page 2036)	*TValueListEditor* is a specialized grid for editing string lists that contain name/value pairs in the form Name=Value. The names and values are stored as a *TStrings* descendant that is the value of the *Strings* property. You can look up the value for any name using the *Values* property. *TValueListEditor* is not available for cross-platform programming. The grid contains two columns, one for the names and one for the values. By default, the Name column is named "Key" and the Value column is named "Value". You can change these defaults by setting the *TitleCaptions* property. You can omit these titles using... more (see page 2036)
Animation Control (see page 2037)	The animation component is a window that silently displays an Audio Video Interleaved (AVI) clip (VCL applications). An AVI clip is a series of bitmap frames, like a movie. Although AVI clips can have sound, animation controls work only with silent AVI clips. The files you use must be either uncompressed AVI files or AVI clips compressed using run-length encoding (RLE). Following are some of the properties of an animation component: • *ResHandle* is the Windows handle for the module that contains the AVI clip as a resource. Set *ResHandle* at runtime to the instance handle or module handle of the... more (see page 2037)
Bevels (see page 2037)	The bevel component (*TBevel*) is a line that can appear raised or lowered. Some components, such as *TPanel*, have built-in properties to create beveled borders. When such properties are unavailable, use *TBevel* to create beveled outlines, boxes, or frames.
Bitmap Buttons (see page 2038)	A bitmap button (*TBitBtn*) is a button control that presents a bitmap image on its face. • To choose a bitmap for your button, set the *Glyph* property. • Use *Kind* to automatically configure a button with a glyph and default behavior. • By default, the glyph appears to the left of any text. To move it, use the *Layout* property. • The glyph and text are automatically centered on the button. To move their position, use the *Margin* property. *Margin* determines the number of pixels between the edge of the image and the edge of the button. • By default, the image... more (see page 2038)

Button Controls (see page 2038)	Users click button controls to initiate actions. You can assign an action to a *TButto*n component by creating an *OnClick* event handler for it. Double-clicking a button at design time takes you to the button's *OnClick* event handler in the Code editor. • Set Cancel to *True* if you want the button to trigger its OnClick event when the user presses Esc. • Set Default to *True* if you want the Enter key to trigger the button's OnClick event.
Buttons and Similar Controls (see page 2038)	Aside from menus, buttons provide the most common way to initiate an action or command in an application. Button-like controls include:
Check Boxes (see page 2039)	A check box is a toggle that lets the user select an on or off state. When the choice is turned on, the check box is checked. Otherwise, the check box is blank. You create check boxes using *TCheckBox*. • Set *Checked* to *True* to make the box appear checked by default. • Set *AllowGrayed* to *True* to give the check box three possible states: checked, unchecked, and grayed. • The *State* property indicates whether the check box is checked (*cbChecked*), unchecked (*cbUnchecked*), or grayed (*cbGrayed*). **Note:** Check box controls display one of two binary states.... more (see page 2039)
Combo Boxes (see page 2039)	A combo box (*TComboBox*) combines an edit box with a scrollable list. When users enter data into the control—by typing or selecting from the list—the value of the *Text* property changes. If *AutoComplete* is enabled, the application looks for and displays the closest match in the list as the user types the data. Three types of combo boxes are: standard, drop-down (the default), and drop-down list.
Cool Bars (VCL Only) (see page 2040)	A cool bar contains child controls that can be moved and resized independently. Each control resides on an individual band. The user positions the controls by dragging the sizing grip to the left of each band. The cool bar requires version 4.70 or later of COMCTL32.DLL (usually located in the Windows\System or Windows\System32 directory) at both design time and runtime. Cool bars cannot be used in cross-platform applications. • The *Bands* property holds a collection of *TCoolBand* objects. At design time, you can add, remove, or modify bands with the Bands editor. To open the Bands editor, select the... more (see page 2040)
Draw Grids (see page 2040)	A draw grid (*TDrawGrid*) displays arbitrary data in tabular format. Write an *OnDrawCell* event handler to fill in the cells of the grid. • The *CellRect* method returns the screen coordinates of a specified cell, while the *MouseToCell* method returns the column and row of the cell at specified screen coordinates. The *Selection* property indicates the boundaries of the currently selected cells. • The *TopRow* property determines which row is currently at the top of the grid. The *LeftCol* property determines the first visible column on the left. *VisibleColCount* and *VisibleRowCount* are the number of columns and rows visible in... more (see page 2040)
Graphic Controls (see page 2040)	The following components make it easy to incorporate graphics into an application.

Group Boxes and Radio Groups (see page 2041)	A group box (*TGroupBox*) arranges related controls on a form. The most commonly grouped controls are radio buttons. After placing a group box on a form, select components from the **Tool palette** and place them in the group box. The *Caption* property contains text that labels the group box at runtime. The radio group component (*TRadioGroup*) simplifies the task of assembling radio buttons and making them work together. To add radio buttons to a radio group, edit the *Items* property in the **Object Inspector**; each string in *Items* makes a radio button appear in the... more (see page 2041)
Grouping Controls (see page 2041)	A graphical interface is easier to use when related controls and information are presented in groups. Components for grouping components include:
List Controls (see page 2042)	Lists present the user with a collection of items to select from. Several components display lists:
Header Controls (see page 2042)	A header control (*THeaderControl*) is a is a set of column headers that the user can select or resize at runtime. Edit the control's *Sections* property to add or modify headers. You can place the header sections above columns or fields. For example, header sections might be placed over a list box (*TListBox*).
Help and Hint Properties (see page 2042)	Most visual controls can display context-sensitive Help as well as fly-by hints at runtime. The *HelpContext* and *HelpFile* properties establish a Help context number and Help file for the control. The *Hint* property contains the text string that appears when the user moves the mouse pointer over a control or menu item. To enable hints, set *ShowHint* to *True*; setting *ParentShowHint* to *True* causes the control's *ShowHint* property to have the same value as its parent's.
Hot Key Controls (VCL Only) (see page 2043)	Use the hot key component (*THotKey*) to assign a keyboard shortcut that transfers focus to any control. The HotKey property contains the current key combination and the *Modifiers* property determines which keys are available for *HotKey*. The hot key component can be assigned as the *ShortCut* property of a menu item. Then, when a user enters the key combination specified by the *HotKey* and *Modifiers* properties, Windows activates the menu item.
Images (see page 2043)	The image component (*TImage*) displays a graphical image, like a bitmap, icon, or metafile. The *Picture* property determines the graphic to be displayed. Use *Center, AutoSize, Stretch*, and *Transparent* to set display options. For more information, see Overview of Graphics Programming (see page 2176).
Labels (see page 2043)	Labels display text and are usually placed next to other controls.
List Boxes and Check-list Boxes (see page 2044)	List boxes (*TListBox*) and check-list boxes display lists from which users can select one or more choices from a list of possible options. The choices are represented using text, graphics, or both. • *Items* uses a *TStrings* object to fill the control with values. • *ItemIndex* indicates which item in the list is selected. • *MultiSelect* specifies whether a user can select more than one item at a time. • *Sorted* determines whether the list is arranged alphabetically. • *Columns* specifies the number of columns in the list control. • *IntegralHeight* specifies whether the list box shows only entries that fit completely in the... more (see page 2044)

List Views (see page 2044)	List views, created using *TListView*, display lists in various formats. Use the *ViewStyle* property to choose the kind of list you want: • *vsIcon* and *vsSmallIcon* display each item as an icon with a label. Users can drag items within the list view window (VCL only). • *vsList* displays items as labeled icons that cannot be dragged. • *vsReport* displays items on separate lines with information arranged in columns. The leftmost column contains a small icon and label, and subsequent columns contain subitems specified by the application. Use the *ShowColumnHeaders* property to display headers for the columns.
Memo and Rich Edit Controls (see page 2044)	Both the *TMemo* and *TRichEdit* controls handle multiple lines of text. *TMemo* is another type of edit box that handles multiple lines of text. The lines in a memo control can extend beyond the right boundary of the edit box, or they can wrap onto the next line. You control whether the lines wrap using the *WordWrap* property. *TRichEdit* is a memo control that supports rich text formatting, printing, searching, and drag-and-drop of text. It allows you to specify font properties, alignment, tabs, indentation, and numbering. **Note:** The rich edit control is available for VCL applications only. In addition to... more (see page 2044)
Page Controls (see page 2045)	The page control component (*TPageControl*) is a page set suitable for multipage dialog boxes. A page control displays multiple overlapping pages that are *TTabSheet* objects. A page is selected in the user interface by clicking a tab on top of the control. To create a new page in a page control at design time, right-click the control and choose New Page. At runtime, you add new pages by creating the object for the page and setting its *PageControl* property:
Paint Boxes (see page 2045)	The paint box (*TPaintBox*) allows your application to draw on a form. Write an *OnPaint* event handler to render an image directly on the paint box's *Canvas*. Drawing outside the boundaries of the paint box is prevented. For more information, see Overview of Graphics Programming (see page 2176).
Panels (see page 2046)	The *TPanel* component provides a generic container for other controls. Panels are typically used to visually group components together on a form. Panels can be aligned with the form to maintain the same relative position when the form is resized. The *BorderWidth* property determines the width, in pixels, of the border around a panel. You can also place other controls onto a panel and use the *Align* property to ensure proper positioning of all the controls in the group on the form. You can make a panel alTop aligned so that its position will remain in place even if the... more (see page 2046)
Progress Bars (see page 2046)	When your application performs a time-consuming operation, you can use a progress bar (*TProgressBar*) to show how much of the task is completed. A progress bar displays a dotted line that grows from left to right. The *Position* property tracks the length of the dotted line. *Max* and *Min* determine the range of *Position*. To make the line grow, increment *Position* by calling the *StepBy* or *StepIt* method. The *Step* property determines the increment used by *StepIt*.
Radio Buttons (see page 2046)	Radio buttons, also called option buttons, present a set of mutually exclusive choices. You can create individual radio buttons using *TRadioButton* or use the *radio group* component (*TRadioGroup*) to arrange radio buttons into groups automatically. You can group radio buttons to let the user select one from a limited set of choices. See Grouping Controls (see page 2041) for more information. A selected radio button is displayed as a circle filled in the middle. When not selected, the radio button shows an empty circle. Assign the value *True* or *False* to the Checked property to change the radio button's visual state.... more (see page 2046)

Scroll Bars (see page 2046)	The scroll bar component creates a scroll bar that you can use to scroll the contents of a window, form, or other control. In the *OnScroll* event handler, you write code that determines how the control behaves when the user moves the scroll bar. The scroll bar component is not used very often, because many visual components include scroll bars of their own and thus don't require additional coding. For example, *TForm* has *VertScrollBar* and *HorzScrollBar* properties that automatically configure scroll bars on the form. To create a scrollable region within a form, use *TScrollBox*.
Scroll Boxes (see page 2047)	Scroll boxes (*TScrollBox*) create scrolling areas within a form. Applications often need to display more information than will fit in a particular area. Some controls—such as list boxes, memos, and forms themselves—can automatically scroll their contents. Another use of scroll boxes is to create multiple scrolling areas (views) in a window. Views are common in commercial word-processor, spreadsheet, and project management applications. Scroll boxes give you the additional flexibility to define arbitrary scrolling subregions of a form. Like panels and group boxes, scroll boxes contain other controls, such as *TButton* and *TCheckBox* objects. But a scroll box is... more (see page 2047)
Shapes (see page 2047)	The shape component displays a geometric shape. It is a nonwindowed control and therefore, cannot receive user input. The *Shape* property determines which shape the control assumes. To change the shape's color or add a pattern, use the *Brush* property, which holds a *TBrush* object. How the shape is painted depends on the *Color* and *Style* properties of *TBrush*.
Specialized Input Controls (see page 2047)	The following components provide additional ways of capturing input.
Speed Buttons (see page 2048)	Speed buttons (TSpeedButton), which usually have images on their faces, can function in groups. They are commonly used with panels to create toolbars. • To make speed buttons act as a group, give the *GroupIndex* property of all the buttons the same nonzero value. • By default, speed buttons appear in an up (unselected) state. To initially display a speed button as selected, set the *Down* property to *True*. • If *AllowAllUp* is *True*, all of the speed buttons in a group can be unselected. Set *AllowAllUp* to *False* if you want a group of buttons to act like a radio... more (see page 2048)
Splitter Controls (see page 2048)	A splitter (*TSplitter*) placed between aligned controls allows users to resize the controls. Used with components like panels and group boxes, splitters let you divide a form into several panes with multiple controls on each pane. After placing a panel or other control on a form, add a splitter with the same alignment as the control. The last control should be client-aligned, so that it fills up the remaining space when the others are resized. For example, you can place a panel at the left edge of a form, set its *Alignment to alLeft*, then place a... more (see page 2048)
Status Bars (see page 2048)	Although you can use a panel to make a status bar, it is simpler to use the *TStatusBar* component. By default, the status bar's *Align* property is set to *alBottom*, which takes care of both position and size. If you only want to display one text string at a time in the status bar, set its *SimplePanel* property to *True* and use the *SimpleText* property to control the text displayed in the status bar. You can also divide a status bar into several text areas, called panels. To create panels, edit the *Panels* property in the **Object Inspector**,... more (see page 2048)
String Grids (see page 2049)	The string grid component is a descendant of *TDrawGrid* that adds specialized functionality to simplify the display of strings. The *Cells* property lists the strings for each cell in the grid; the *Objects* property lists objects associated with each string. All the strings and associated objects for a particular column or row can be accessed through the *Cols* or *Rows* property.
Tab Controls (see page 2049)	The tab control component (*TTabControl*) creates a set of tabs that look like notebook dividers. You can create tabs by editing the *Tabs* property in the **Object Inspector**; each string in *Tabs* represents a tab. The tab control is a single panel with one set of components on it. To change the appearance of the control when the tabs are clicked, you need to write an *OnChange* event handler. To create a multipage dialog box, use a page control instead.

Grids (see page 2049)	Grids display information in rows and columns. If you're writing a database application, use the TDBCtrlGrid or TDBCtrlGrid component. Otherwise, use a standard draw grid or string grid.
Edit Controls (see page 2049)	Edit controls display text to the user and allow the user to enter text. The type of control used for this purpose depends on the size and format of the information.
Toolbar Controls (see page 2050)	Toolbars provide an easy way to arrange and manage visual controls. You can create a toolbar out of a panel component and speed buttons, or you can use the *TToolBar* component, then right-click and choose New Button to add buttons to the toolbar. The *TToolBar* component has several advantages: buttons on a toolbar automatically maintain uniform dimensions and spacing; other controls maintain their relative position and height; controls can automatically wrap around to start a new row when they do not fit horizontally; and *TToolBar* offers display options like transparency, pop-up borders, and spaces and dividers to group controls. You... more (see page 2050)
Track Bars (see page 2051)	A track bar can set integer values on a continuous range. It is useful for adjusting properties like color, volume and brightness. The user moves the slide indicator by dragging it to a particular location or clicking within the bar. • Use the *Max* and *Min* properties to set the upper and lower range of the track bar. • Use *SelEnd* and *SelStart* to highlight a selection range. • The *Orientation* property determines whether the track bar is vertical or horizontal. • By default, a track bar has one row of ticks along the bottom. Use the *TickMarks* property to change their location. To... more (see page 2051)
Tree Views (see page 2051)	A tree view *(TTreeView)* displays items in an indented outline. The control provides buttons that allow nodes to be expanded and collapsed. You can include icons with items' text labels and display different icons to indicate whether a node is expanded or collapsed. You can also include graphics, such as check boxes, that reflect state information about the items. • *Indent* sets the number of pixels horizontally separating items from their parents. • *ShowButtons* enables the display of "+" and "–" buttons to indicate whether an item can be expanded. • *ShowLines* enables display of connecting lines to show hierarchical relationships... more (see page 2051)
Up-down Controls (VCL Only) (see page 2052)	In VCL applications only, an up-down control (*TUpDown*) consists of a pair of arrow buttons that allow users to change an integer value in fixed increments. The current value is given by the *Position* property; the increment, which defaults to 1, is specified by the *Increment* property. Use the *Associate* property to attach another component (such as an edit control) to the up-down control.
Display Controls (see page 2052)	There are many ways to provide users with information about the state of an application. For example, some components—including *TForm*—have a *Caption* property that can be set at runtime. You can also create dialog boxes to display messages. In addition, the following components are especially useful for providing visual feedback at runtime to identify the object.
Text Controls (see page 2052)	Many applications use text controls to display text to the user. You can use: • Edit controls (see page 2049), which allow the user to add text. • Text viewing controls (see page 2052) and labels (see page 2043), which do not allow user to add text.
Text Viewing Controls (see page 2052)	

3.2.4.7.1 Value List Editors (VCL Only)

TValueListEditor is a specialized grid for editing string lists that contain name/value pairs in the form Name=Value. The names and values are stored as a *TStrings* descendant that is the value of the *Strings* property. You can look up the value for any name

using the *Values* property. *TValueListEditor* is not available for cross-platform programming.

The grid contains two columns, one for the names and one for the values. By default, the Name column is named "Key" and the Value column is named "Value". You can change these defaults by setting the *TitleCaptions* property. You can omit these titles using the *DisplayOptions* property (which also controls resize when you resize the control.)

You can control whether users can edit the Name column using the *KeyOptions* property. *KeyOptions* contains separate options to allow editing, adding new names, deleting names, and controlling whether new names must be unique.

You can control how users edit the entries in the Value column using the *ItemProps* property. Each item has a separate *TItemProp* object that lets you

- Supply an edit mask to limit the valid input.
- Specify a maximum length for values.
- Mark the value as read-only.
- Specify that the value list editor displays a drop-down arrow that opens a pick list of values from which the user can choose or an ellipsis button that triggers an event you can use for displaying a dialog in which users enter values.

If you specify that there is a drop-down arrow, you must supply the list of values from which the user chooses. These can be a static list (the *PickList* property of the *TItemProp* object) or they can be dynamically added at runtime using the value list editor's *OnGetPickList* event. You can also combine these approaches and have a static list that the *OnGetPickList* event handler modifies.

If you specify that there is an ellipsis button, you must supply the response that occurs when the user clicks that button (including the setting of a value, if appropriate). You provide this response by writing an *OnEditButtonClick* event handler.

TValueListEditor

3.2.4.7.2 Animation Control

The animation component is a window that silently displays an Audio Video Interleaved (AVI) clip (VCL applications). An AVI clip is a series of bitmap frames, like a movie. Although AVI clips can have sound, animation controls work only with silent AVI clips. The files you use must be either uncompressed AVI files or AVI clips compressed using run-length encoding (RLE).

Following are some of the properties of an animation component:

- *ResHandle* is the Windows handle for the module that contains the AVI clip as a resource. Set *ResHandle* at runtime to the instance handle or module handle of the module that includes the animation resource. After setting *ResHandle*, set the *ResID* or *ResName* property to specify which resource in the indicated module is the AVI clip that should be displayed by the animation control.
- Set *AutoSize* to *True* to have the animation control adjust its size to the size of the frames in the AVI clip.
- *StartFrame* and *StopFrame* specify in which frames to start and stop the clip.
- Set *CommonAVI* to display one of the common Windows AVI clips provided in Shell32.DLL.
- Specify when to start and interrupt the animation by setting the *Active* property to *True* and *False*, respectively, and how many repetitions to play by setting the *Repetitions* property.
- The *Timers* property lets you display the frames using a timer. This is useful for synchronizing the animation sequence with other actions, such as playing a sound track.

TAnimate

3.2.4.7.3 Bevels

The bevel component (*TBevel*) is a line that can appear raised or lowered. Some components, such as *TPanel*, have built-in

properties to create beveled borders. When such properties are unavailable, use *TBevel* to create beveled outlines, boxes, or frames.

See Also

TBevel

3.2.4.7.4 Bitmap Buttons

A bitmap button (*TBitBtn*) is a button control that presents a bitmap image on its face.

- To choose a bitmap for your button, set the *Glyph* property.
- Use *Kind* to automatically configure a button with a glyph and default behavior.
- By default, the glyph appears to the left of any text. To move it, use the *Layout* property.
- The glyph and text are automatically centered on the button. To move their position, use the *Margin* property. *Margin* determines the number of pixels between the edge of the image and the edge of the button.
- By default, the image and the text are separated by 4 pixels. Use *Spacing* to increase or decrease the distance.
- Bitmap buttons can have 3 states: up, down, and held down. Set the *NumGlyphs* property to 3 to show a different bitmap for each state.

See Also

TBitBtn

3.2.4.7.5 Button Controls

Users click button controls to initiate actions. You can assign an action to a *TButto*n component by creating an *OnClick* event handler for it. Double-clicking a button at design time takes you to the button's *OnClick* event handler in the Code editor.

- Set Cancel to *True* if you want the button to trigger its OnClick event when the user presses Esc.
- Set Default to *True* if you want the Enter key to trigger the button's OnClick event.

See Also

TButton

3.2.4.7.6 Buttons and Similar Controls

Aside from menus, buttons provide the most common way to initiate an action or command in an application. Button-like controls include:

Use this component:	To do this:
TButton	Present command choices on buttons with text
TBitBtn	Present command choices on buttons with text and glyphs
TSpeedButton	Create grouped toolbar buttons
TCheckBox	Present on/off options
TRadioButton	Present a set of mutually exclusive choices
TToolBar	Arrange tool buttons and other controls in rows and automatically adjust their sizes and positions
TCoolBar	Display a collection of windowed controls within movable, resizable bands (VCL only)

Action lists let you centralize responses to user commands (actions) for objects such as menus and buttons that respond to

those commands. See Using action lists (see page 2007) for details on how to use action lists with buttons, toolbars, and menus.

You can custom draw buttons individually or application wide. See Developing the user interface. (see page 1983)

3.2.4.7.7 Check Boxes

A check box is a toggle that lets the user select an on or off state. When the choice is turned on, the check box is checked. Otherwise, the check box is blank. You create check boxes using *TCheckBox*.

- Set *Checked* to *True* to make the box appear checked by default.
- Set *AllowGrayed* to *True* to give the check box three possible states: checked, unchecked, and grayed.
- The *State* property indicates whether the check box is checked (*cbChecked*), unchecked (*cbUnchecked*), or grayed (*cbGrayed*).

  Note: Check box controls display one of two binary states. The indeterminate state is used when other settings make it impossible to determine the current value for the check box.

See Also

TCheckBox

TDBCheckBox

3.2.4.7.8 Combo Boxes

A combo box (*TComboBox*) combines an edit box with a scrollable list. When users enter data into the control—by typing or selecting from the list—the value of the *Text* property changes. If *AutoComplete* is enabled, the application looks for and displays the closest match in the list as the user types the data.

Three types of combo boxes are: standard, drop-down (the default), and drop-down list.

To create a combo box

1. Set the *Style* property to select the type of combo box you need:

- Use *csDropDown* to create an edit box with a drop-down list. Use *csDropDownList* to make the edit box read-only (forcing users to choose from the list).
- Use *csOwnerDrawFixed* or *csOwnerDrawVariable* to create *owner-draw* combo boxes that display items graphically or in varying heights. For information on owner-draw controls, see Adding Graphics to Controls (see page 2154).
- Use *csSimple* to create a combo box with a fixed list that does not close. Be sure to resize the combo box so that the list items are displayed (VCL only).

2. Set the *DropDownCount* property to change the number of items displayed in the list.

See Also

TComboBox

3.2.4.7.9 Cool Bars (VCL Only)

A cool bar contains child controls that can be moved and resized independently. Each control resides on an individual band. The user positions the controls by dragging the sizing grip to the left of each band.

The cool bar requires version 4.70 or later of COMCTL32.DLL (usually located in the Windows\System or Windows\System32 directory) at both design time and runtime. Cool bars cannot be used in cross-platform applications.

- The *Bands* property holds a collection of *TCoolBand* objects. At design time, you can add, remove, or modify bands with the Bands editor. To open the Bands editor, select the *Bands* property in the **Object Inspector**, then double-click in the Value column to the right, or click the ellipsis (...) button. You can also create bands by adding new windowed controls from the palette.
- The *FixedOrder* property determines whether users can reorder the bands.
- The *FixedSize* property determines whether the bands maintain a uniform height.

See Also

TCoolBar

3.2.4.7.10 Draw Grids

A draw grid (*TDrawGrid*) displays arbitrary data in tabular format. Write an *OnDrawCell* event handler to fill in the cells of the grid.

- The *CellRect* method returns the screen coordinates of a specified cell, while the *MouseToCell* method returns the column and row of the cell at specified screen coordinates. The *Selection* property indicates the boundaries of the currently selected cells.
- The *TopRow* property determines which row is currently at the top of the grid. The *LeftCol* property determines the first visible column on the left. *VisibleColCount* and *VisibleRowCount* are the number of columns and rows visible in the grid.
- You can change the width or height of a column or row with the *ColWidths* and *RowHeights* properties. Set the width of the grid lines with the *GridLineWidth* property. Add scroll bars to the grid with the *ScrollBars* property.
- You can choose to have fixed or non-scrolling columns and rows with the *FixedCols* and *FixedRows* properties. Assign a color to the fixed columns and rows with the *FixedColor* property.
- The *Options*, *DefaultColWidth*, and *DefaultRowHeight* properties also affect the appearance and behavior of the grid.

TDrawGrid

3.2.4.7.11 Graphic Controls

The following components make it easy to incorporate graphics into an application.

Use this component:	To display:
TImage	Graphics files
TShape	Geometric shapes
TBevel	3-D lines and frames
TPaintBox	Graphics drawn by your program at runtime
TAnimate	AVI files (VCL applications)

Notice that these include common paint routines (*Repaint, Invalidate*, and so on) that never need to receive focus.

To create a graphic control, see Creating a graphic control (see page 1220).

See Also

TGraphic

3.2.4.7.12 Group Boxes and Radio Groups

A group box (*TGroupBox*) arranges related controls on a form. The most commonly grouped controls are radio buttons. After placing a group box on a form, select components from the **Tool palette** and place them in the group box. The *Caption* property contains text that labels the group box at runtime.

The radio group component (*TRadioGroup*) simplifies the task of assembling radio buttons and making them work together. To add radio buttons to a radio group, edit the *Items* property in the **Object Inspector**; each string in *Items* makes a radio button appear in the group box with the string as its caption. The value of the *ItemIndex* property determines which radio button is currently selected. Display the radio buttons in a single column or in multiple columns by setting the value of the *Columns* property. To respace the buttons, resize the radio group component.

See Also

TGroupBox

TRadioGroup

TRadioButton

3.2.4.7.13 Grouping Controls

A graphical interface is easier to use when related controls and information are presented in groups. Components for grouping components include:

Use this component:	When you want this:
TGroupBox	A standard group box with a title
TRadioGroup	A simple group of radio buttons
TPanel	A more visually flexible group of controls
TScrollBox	A scrollable region containing controls
TTabControl	A set of mutually exclusive notebook-style tabs
TPageControl	A set of mutually exclusive notebook-style tabs with corresponding pages, each of which may contain other controls
THeaderControl	Resizable column headers

TScrollBox

TTabControl

TPageControl

THeaderControl

Splitter Control (see page 2048)

3.2.4.7.14 List Controls

Lists present the user with a collection of items to select from. Several components display lists:

Use this component:	To display:
TListBox	A list of text strings
TCheckListBox	A list with a check box in front of each item
TComboBox	An edit box with a scrollable drop-down list
TTreeView	A hierarchical list
TListView	A list of (draggable) items with optional icons, columns, and headings
TDateTimePicker	A list box for entering dates or times (VCL applications only)
TMonthCalendar	A calendar for selecting dates (VCL applications only)

Use the nonvisual *TStringList* and *TImageList* components to manage sets of strings and images. For more information about string lists, see Working with string lists (see page 2140).

See Also

TImageList

TStringList

3.2.4.7.15 Header Controls

A header control (*THeaderControl*) is a is a set of column headers that the user can select or resize at runtime. Edit the control's *Sections* property to add or modify headers. You can place the header sections above columns or fields. For example, header sections might be placed over a list box (*TListBox*).

See Also

THeaderControl

3.2.4.7.16 Help and Hint Properties

Most visual controls can display context-sensitive Help as well as fly-by hints at runtime. The *HelpContext* and *HelpFile* properties establish a Help context number and Help file for the control.

The *Hint* property contains the text string that appears when the user moves the mouse pointer over a control or menu item. To enable hints, set *ShowHint* to *True*; setting *ParentShowHint* to *True* causes the control's *ShowHint* property to have the same value as its parent's.

See Also

THintWindow

TWinControl

HelpContext

3.2.4.7.17 Hot Key Controls (VCL Only)

Use the hot key component (*THotKey*) to assign a keyboard shortcut that transfers focus to any control. The HotKey property contains the current key combination and the *Modifiers* property determines which keys are available for *HotKey*.

The hot key component can be assigned as the *ShortCut* property of a menu item. Then, when a user enters the key combination specified by the *HotKey* and *Modifiers* properties, Windows activates the menu item.

See Also

THotKey

3.2.4.7.18 Images

The image component (*TImage*) displays a graphical image, like a bitmap, icon, or metafile. The *Picture* property determines the graphic to be displayed. Use *Center, AutoSize, Stretch*, and *Transparent* to set display options. For more information, see Overview of Graphics Programming (see page 2176).

See Also

TImage

3.2.4.7.19 Labels

Labels display text and are usually placed next to other controls.

Use this component:	When you want users to do this:
TLabel	Display text on a nonwindowed control.
TStaticText	Display text on a windowed control.

You place a label on a form when you need to identify or annotate another component such as an edit box or when you want to include text on a form. The standard label component, *TLabel*, is a non-windowed control, so it cannot receive focus; when you need a label with a window handle, use *TStaticText* instead.

Label properties include the following:

- *Caption* contains the text string for the label.
- *Font*, *Color*, and other properties determine the appearance of the label. Each label can use only one typeface, size, and color.
- *FocusControl* links the label to another control on the form. If *Caption* includes an accelerator key, the control specified by *FocusControl* receives focus when the user presses the accelerator key.
- *ShowAccelChar* determines whether the label can display an underlined accelerator character. If *ShowAccelChar* is *True*, any character preceded by an ampersand (&) appears underlined and enables an accelerator key.
- *Transparent* determines whether items under the label (such as graphics) are visible.

Labels usually display read-only static text that cannot be changed by the application user. The application can change the text while it is executing by assigning a new value to the *Caption* property. To add a text object to a form that a user can scroll or edit, use *TEdit*.

See Also

TLabel

TStaticText

3.2.4.7.20 List Boxes and Check-list Boxes

List boxes (*TListBox*) and check-list boxes display lists from which users can select one or more choices from a list of possible options. The choices are represented using text, graphics, or both.

- *Items* uses a *TStrings* object to fill the control with values.
- *ItemIndex* indicates which item in the list is selected.
- *MultiSelect* specifies whether a user can select more than one item at a time.
- *Sorted* determines whether the list is arranged alphabetically.
- *Columns* specifies the number of columns in the list control.
- *IntegralHeight* specifies whether the list box shows only entries that fit completely in the vertical space (VCL only).
- *ItemHeight* specifies the height of each item in pixels. The *Style* property can cause *ItemHeight* to be ignored.
- The *Style* property determines how a list control displays its items. By default, items are displayed as strings. By changing the value of *Style*, you can create *owner-draw* list boxes that display items graphically or in varying heights. For information on owner-draw controls, see Adding Graphics to Controls (see page 2154).

To create a simple list box

1. Within your project, drop a list box component from the **Tool palette** onto a form.
2. Size the list box and set its alignment as needed.
3. Double-click the right side of the *Items* property or choose the ellipsis button to display the String List Editor.
4. Use the editor to enter free form text arranged in lines for the contents of the list box.
5. Then choose OK.

To let users select multiple items in the list box, you can use the *ExtendedSelect* and *MultiSelect* properties.

See Also

TListBox

TCheckListBox

3.2.4.7.21 List Views

List views, created using *TListView*, display lists in various formats. Use the *ViewStyle* property to choose the kind of list you want:

- *vsIcon* and *vsSmallIcon* display each item as an icon with a label. Users can drag items within the list view window (VCL only).
- *vsList* displays items as labeled icons that cannot be dragged.
- *vsReport* displays items on separate lines with information arranged in columns. The leftmost column contains a small icon and label, and subsequent columns contain subitems specified by the application. Use the *ShowColumnHeaders* property to display headers for the columns.

See Also

TListView

3.2.4.7.22 Memo and Rich Edit Controls

Both the *TMemo* and *TRichEdit* controls handle multiple lines of text.

TMemo is another type of edit box that handles multiple lines of text. The lines in a memo control can extend beyond the right boundary of the edit box, or they can wrap onto the next line. You control whether the lines wrap using the *WordWrap* property.

TRichEdit is a memo control that supports rich text formatting, printing, searching, and drag-and-drop of text. It allows you to specify font properties, alignment, tabs, indentation, and numbering.

Note: The rich edit control is available for VCL applications only.

In addition to the properties that all edit controls (see page 2049) have, memo and rich edit controls include other properties, such as the following:

- *Alignment* specifies how text is aligned (left, right, or center) in the component.
- The *Text* property contains the text in the control. Your application can tell if the text changes by checking the Modified property.
- *Lines* contains the text as a list of strings.
- *OEMConvert* determines whether the text is temporarily converted from ANSI to OEM as it is entered. This is useful for validating file names (VCL only).
- *WordWrap* determines whether the text will wrap at the right margin.
- *WantReturns* determines whether the user can insert hard returns in the text.
- *WantTabs* determines whether the user can insert tabs in the text.
- *AutoSelect* determines whether the text is automatically selected (highlighted) when the control becomes active.

At runtime, you can select all the text in the memo with the *SelectAll* method.

Note: Under Windows 9x both Memo and Rich Edit controls are limited to storing 64 kb of data.

See Also

TMemo

TRichEdit

3.2.4.7.23 Page Controls

The page control component (*TPageControl*) is a page set suitable for multipage dialog boxes. A page control displays multiple overlapping pages that are *TTabSheet* objects. A page is selected in the user interface by clicking a tab on top of the control.

To create a new page in a page control at design time, right-click the control and choose New Page. At runtime, you add new pages by creating the object for the page and setting its *PageControl* property:

```
NewTabSheet = TTabSheet.Create(PageControl1);
NewTabSheet.PageControl := PageControl1;
TTabSheet *pTabSheet = new TTabSheet(PageControl1);
pTabSheet->PageControl = PageControl1;
```

To access the active page, use the *ActivePage* property. To change the active page, you can set either the *ActivePage* or the *ActivePageIndex* property.

See Also

TPageControl

3.2.4.7.24 Paint Boxes

The paint box (*TPaintBox*) allows your application to draw on a form. Write an *OnPaint* event handler to render an image directly on the paint box's *Canvas*. Drawing outside the boundaries of the paint box is prevented. For more information, see Overview of Graphics Programming (see page 2176).

See Also

TPaintBox

3.2.4.7.25 Panels

The *TPanel* component provides a generic container for other controls. Panels are typically used to visually group components together on a form. Panels can be aligned with the form to maintain the same relative position when the form is resized. The *BorderWidth* property determines the width, in pixels, of the border around a panel.

You can also place other controls onto a panel and use the *Align* property to ensure proper positioning of all the controls in the group on the form. You can make a panel alTop aligned so that its position will remain in place even if the form is resized.

The look of the panel can be changed to a raised or lowered look by using the *BevelOuter* and *BevelInner* properties. You can vary the values of these properties to create different visual 3-D effects. Note that if you merely want a raised or lowered bevel, you can use the less resource intensive *TBevel* control instead.

You can also use one or more panels to build various status bars or information display areas.

See Also

TPanel

Splitter Control (see page 2048)

3.2.4.7.26 Progress Bars

When your application performs a time-consuming operation, you can use a progress bar (*TProgressBar*) to show how much of the task is completed. A progress bar displays a dotted line that grows from left to right.

The *Position* property tracks the length of the dotted line. *Max* and *Min* determine the range of *Position*. To make the line grow, increment *Position* by calling the *StepBy* or *StepIt* method. The *Step* property determines the increment used by *StepIt*.

See Also

TProgressBar

Track Bar Controls (see page 2051)

3.2.4.7.27 Radio Buttons

Radio buttons, also called option buttons, present a set of mutually exclusive choices. You can create individual radio buttons using *TRadioButton* or use the *radio group* component (*TRadioGroup*) to arrange radio buttons into groups automatically. You can group radio buttons to let the user select one from a limited set of choices. See Grouping Controls (see page 2041) for more information.

A selected radio button is displayed as a circle filled in the middle. When not selected, the radio button shows an empty circle. Assign the value *True* or *False* to the Checked property to change the radio button's visual state.

See Also

TRadioButton

3.2.4.7.28 Scroll Bars

The scroll bar component creates a scroll bar that you can use to scroll the contents of a window, form, or other control. In the *OnScroll* event handler, you write code that determines how the control behaves when the user moves the scroll bar.

The scroll bar component is not used very often, because many visual components include scroll bars of their own and thus don't require additional coding. For example, *TForm* has *VertScrollBar* and *HorzScrollBar* properties that automatically configure scroll bars on the form. To create a scrollable region within a form, use *TScrollBox*.

See Also

TScrollBar

Header Controls (see page 2042)

3.2.4.7.29 Scroll Boxes

Scroll boxes (*TScrollBox*) create scrolling areas within a form. Applications often need to display more information than will fit in a particular area. Some controls—such as list boxes, memos, and forms themselves—can automatically scroll their contents.

Another use of scroll boxes is to create multiple scrolling areas (views) in a window. Views are common in commercial word-processor, spreadsheet, and project management applications. Scroll boxes give you the additional flexibility to define arbitrary scrolling subregions of a form.

Like panels and group boxes, scroll boxes contain other controls, such as *TButton* and *TCheckBox* objects. But a scroll box is normally invisible. If the controls in the scroll box cannot fit in its visible area, the scroll box automatically displays scroll bars.

Another use of a scroll box is to restrict scrolling in areas of a window, such as a toolbar or status bar (*TPanel* components). To prevent a toolbar and status bar from scrolling, hide the scroll bars, and then position a scroll box in the client area of the window between the toolbar and status bar. The scroll bars associated with the scroll box will appear to belong to the window, but will scroll only the area inside the scroll box.

See Also

TScrollBox

3.2.4.7.30 Shapes

The shape component displays a geometric shape. It is a nonwindowed control and therefore, cannot receive user input. The *Shape* property determines which shape the control assumes. To change the shape's color or add a pattern, use the *Brush* property, which holds a *TBrush* object. How the shape is painted depends on the *Color* and *Style* properties of *TBrush*.

See Also

TShape

TBrush

3.2.4.7.31 Specialized Input Controls

The following components provide additional ways of capturing input.

Use this component:	When you want users to do this:
TScrollBar	Select values on a continuous range
TTrackBar	Select values on a continuous range (more visually effective than a scroll bar)
TUpDown	Select a value from a spinner attached to an edit component (VCL applications only)
THotKey	Enter `Ctrl/ Shift/ Alt` keyboard sequences (VCL applications only)

3.2.4.7.32 Speed Buttons

Speed buttons (TSpeedButton), which usually have images on their faces, can function in groups. They are commonly used with panels to create toolbars.

- To make speed buttons act as a group, give the *GroupIndex* property of all the buttons the same nonzero value.
- By default, speed buttons appear in an up (unselected) state. To initially display a speed button as selected, set the *Down* property to *True*.
- If *AllowAllUp* is *True*, all of the speed buttons in a group can be unselected. Set *AllowAllUp* to *False* if you want a group of buttons to act like a radio group.

See Also

TSpeedButton

Adding a Toolbar Using a Panel Component (see page 1969)

Adding a Speed Button to a Panel (see page 1969)

Assigning a Speed Button's Glyph (see page 1972)

Setting the Initial Condition of a Speed Button (see page 2004)

Creating a Group of Speed Buttons (see page 1979)

3.2.4.7.33 Splitter Controls

A splitter (*TSplitter*) placed between aligned controls allows users to resize the controls. Used with components like panels and group boxes, splitters let you divide a form into several panes with multiple controls on each pane.

After placing a panel or other control on a form, add a splitter with the same alignment as the control. The last control should be client-aligned, so that it fills up the remaining space when the others are resized. For example, you can place a panel at the left edge of a form, set its *Alignment to alLeft*, then place a splitter (also aligned to *alLeft*) to the right of the panel, and finally place another panel (aligned to *alLeft* or *alClient*) to the right of the splitter.

Set *MinSize* to specify a minimum size the splitter must leave when resizing its neighboring control. Set *Beveled* to *True* to give the splitter's edge a 3D look.

See Also

TSplitter

Grouping Controls (see page 2041)

3.2.4.7.34 Status Bars

Although you can use a panel to make a status bar, it is simpler to use the *TStatusBar* component. By default, the status bar's *Align* property is set to *alBottom*, which takes care of both position and size.

If you only want to display one text string at a time in the status bar, set its *SimplePanel* property to *True* and use the *SimpleText* property to control the text displayed in the status bar.

You can also divide a status bar into several text areas, called panels. To create panels, edit the *Panels* property in the **Object Inspector**, setting each panel's *Width*, *Alignment*, and *Text* properties from the Panels editor. Each panel's *Text* property contains the text displayed in the panel.

See Also

TStatusBar

Panels (see page 2046)

3.2.4.7.35 String Grids

The string grid component is a descendant of *TDrawGrid* that adds specialized functionality to simplify the display of strings. The *Cells* property lists the strings for each cell in the grid; the *Objects* property lists objects associated with each string. All the strings and associated objects for a particular column or row can be accessed through the *Cols* or *Rows* property.

See Also

TStringGrid

3.2.4.7.36 Tab Controls

The tab control component (*TTabControl*) creates a set of tabs that look like notebook dividers. You can create tabs by editing the *Tabs* property in the **Object Inspector**; each string in *Tabs* represents a tab. The tab control is a single panel with one set of components on it. To change the appearance of the control when the tabs are clicked, you need to write an *OnChange* event handler. To create a multipage dialog box, use a page control instead.

See Also

TTabControl

TPageControl

3.2.4.7.37 Grids

Grids display information in rows and columns. If you're writing a database application, use the TDBCtrlGrid or TDBCtrlGrid component. Otherwise, use a standard draw grid or string grid.

See Also

TDrawGrid

TStringGrid

TDBGrid

3.2.4.7.38 Edit Controls

Edit controls display text to the user and allow the user to enter text. The type of control used for this purpose depends on the size and format of the information.

Use this component:	When you want users to do this:
TEdit	Edit a single line of text.
TMemo	Edit multiple lines of text.
TMaskEdit	Adhere to a particular format, such as a postal code or phone number.
TRichEdit	Edit multiple lines of text using rich text format (VCL only).

TEdit and *TMaskEdit* are simple edit controls that include a single line text edit box in which you can type information. When the

edit box has focus, a blinking insertion point appears.

You can include text in the edit box by assigning a string value to its *Text* property. You control the appearance of the text in the edit box by assigning values to its *Font* property. You can specify the typeface, size, color, and attributes of the font. The attributes affect all of the text in the edit box and cannot be applied to individual characters.

An edit box can be designed to change its size depending on the size of the font it contains. You do this by setting the *AutoSize* property to *True*. You can limit the number of characters an edit box can contain by assigning a value to the *MaxLength* property.

TMaskEdit is a special edit control that validates the text entered against a mask that encodes the valid forms the text can take. The mask can also format the text that is displayed to the user.

TMemo and TRichEdit (see page 2044)*controls allow the user to add several lines of text.*

Edit controls have some of the following important properties:

Edit control properties

Property	Description
Text	Determines the text that appears in the edit box or memo control.
Font	Controls the attributes of text written in the edit box or memo control.
AutoSize	Enables the edit box to dynamically change its height depending on the currently selected font.
ReadOnly	Specifies whether the user is allowed to change the text.
MaxLength	Limits the number of characters in simple edit controls.
SelText	Contains the currently selected (highlighted) part of the text.
SelStart, SelLength	Indicate the position and length of the selected part of the text.

TRichEdit

Working with Text in Controls (see page 2168)

Edit Controls

3.2.4.7.39 Toolbar Controls

Toolbars provide an easy way to arrange and manage visual controls. You can create a toolbar out of a panel component and speed buttons, or you can use the *TToolBar* component, then right-click and choose New Button to add buttons to the toolbar.

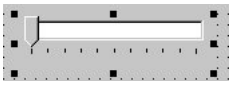
The *TToolBar* component has several advantages: buttons on a toolbar automatically maintain uniform dimensions and spacing; other controls maintain their relative position and height; controls can automatically wrap around to start a new row when they do not fit horizontally; and *TToolBar* offers display options like transparency, pop-up borders, and spaces and dividers to group controls.

You can use a centralized set of actions on toolbars and menus, by using action lists (see page 2007) or action bands (see page 2007).

Toolbars can also parent other controls such as edit boxes, combo boxes, and so on.

See Also

TToolBar



3.2.4.7.40 Track Bars

A track bar can set integer values on a continuous range. It is useful for adjusting properties like color, volume and brightness. The user moves the slide indicator by dragging it to a particular location or clicking within the bar.

- Use the *Max* and *Min* properties to set the upper and lower range of the track bar.
- Use *SelEnd* and *SelStart* to highlight a selection range.
- The *Orientation* property determines whether the track bar is vertical or horizontal.
- By default, a track bar has one row of ticks along the bottom. Use the *TickMarks* property to change their location. To control the intervals between ticks, use the *TickStyle* property and *SetTick* method.

Three views of the track bar component:

- *Position* sets a default position for the track bar and tracks the position at runtime.
- By default, users can move one tick up or down by pressing the up and down arrow keys. Set *LineSize* to change that increment.
- Set *PageSize* to determine the number of ticks moved when the user presses *Page Up* and *Page Down*.

See Also

TTrackBar

3.2.4.7.41 Tree Views

A tree view *(TTreeView*) displays items in an indented outline. The control provides buttons that allow nodes to be expanded and collapsed. You can include icons with items' text labels and display different icons to indicate whether a node is expanded or collapsed. You can also include graphics, such as check boxes, that reflect state information about the items.

- *Indent* sets the number of pixels horizontally separating items from their parents.
- *ShowButtons* enables the display of "+" and "–" buttons to indicate whether an item can be expanded.
- *ShowLines* enables display of connecting lines to show hierarchical relationships (VCL only).
- *ShowRoot* determines whether lines connecting the top-level items are displayed (VCL only).

To add items to a tree view control at design time, double-click on the control to display the TreeView Items editor. The items you add become the value of the *Items* property. You can change the items at runtime by using the methods of the *Items* property, which is an object of type *TTreeNodes*. *TTreeNodes* has methods for adding, deleting, and navigating the items in the tree view.

Tree views can display columns and subitems similar to list views in vsReport mode.

See Also

TTreeView

3.2.4.7.42 Up-down Controls (VCL Only)

In VCL applications only, an up-down control (*TUpDown*) consists of a pair of arrow buttons that allow users to change an integer value in fixed increments. The current value is given by the *Position* property; the increment, which defaults to 1, is specified by the *Increment* property. Use the *Associate* property to attach another component (such as an edit control) to the up-down control.

See Also

TUpDown

3.2.4.7.43 Display Controls

There are many ways to provide users with information about the state of an application. For example, some components—including *TForm*—have a *Caption* property that can be set at runtime. You can also create dialog boxes to display messages. In addition, the following components are especially useful for providing visual feedback at runtime to identify the object.

Use this component or property:	To do this:
TStatusBar	Display a status region (usually at the bottom of a window)
TProgressBar	Show the amount of work completed for a particular task
Hint and ShowHint	Activate fly-by or "tooltip" Help
HelpContext and HelpFile	Link context-sensitive online Help

TStaticText

3.2.4.7.44 Text Controls

Many applications use text controls to display text to the user. You can use:

- Edit controls (see page 2049), which allow the user to add text.
- Text viewing controls (see page 2052) and labels (see page 2043), which do not allow user to add text.

Edit Controls (see page 2049)

Working with Text in Controls (see page 2168)

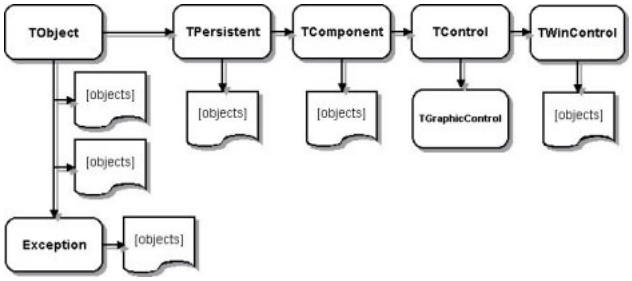
3.2.4.7.45 Text Viewing Controls

Use this component:	When you want users to do this:
TTextBrowser	Display a text file or simple HTML page that users can scroll through.

TTextViewer	Display a text file or simple HTML page. Users can scroll through the page or click links to view other pages and images.
TLCDNumber	Display numeric information in a digital display form.

TTextViewer acts as a simple viewer so that users can read and scroll through documents. With *TTextBrowser*, users can also click links to navigate to other documents and other parts of the same document. Documents visited are stored in a history list, which can be navigated using the *Backward, Forward*, and *Home* methods. *TTextViewer* and *TTextBrowser* are best used to display HTML-based text or to implement an HTML-based Help system.

TTextBrowser has the same properties as *TTextViewer* plus *Factory*. *Factory* determines the MIME factory object used to determine file types for embedded images. For example, you can associate filename extensions—such as .txt, .html, and .xml—with MIME types and have the factory load this data into the control.



Use the *FileName* property to add a text file, such as .html, to appear in the control at runtime.

To see an application using the text browser control, see ..\Delphi7\Demos\Clx\TextBrowser.

3.2.4.8 Understanding the component library

Topics

Name	Description
Understanding the Component Library (see page 2055)	The component library is made up of objects that you can use in your projects. The VCL/RTL contains low-level classes and routines available for all VCL applications. VCL/RTL includes the runtime library (RTL) up to and including the Classes unit. Use the VCL when you want to use native Windows controls, Windows-specific features, or extend an existing VCL application. All classes in the VCL descend from *TObject*. *TObject* introduces methods that implement fundamental behavior like construction, destruction, and message handling. *Components* are a subset of the component library that descend from the class *TComponent*. You can place... more (see page 2055)
Properties, Methods, and Events (see page 2056)	The VCL hierarchy of classes is tied to the IDE, where you can develop applications quickly. The classes in the VCL are based on properties, methods, and events. Each class includes data members (properties), functions that operate on the data (methods), and a way to interact with users of the class (events). The VCL component library is written in the Delphi language, and it is based on the Windows API.
Types of Events (see page 2057)	The kinds of events that can occur can be divided into two main categories: • User events • System events • Internal events

Objects, Components, and Controls (see page 2057)	The following diagram is a greatly simplified view of the inheritance hierarchy that illustrates the relationship between objects, components, and controls.  Every object (class) inherits from *TObject*. Objects that can appear in the Form Designer inherit from *TPersistent* or *TComponent*. Controls, which appear to the user at runtime, inherit from *TControl*. There are two types of controls, graphic controls, which inherit from *TGraphicControl*, and windowed controls, which inherit from *TWinControl* or *TWidgetControl*. A control like *TCheckBox* inherits all the functionality of *TObject*, *TPersistent*, *TComponent*, *TControl*, and... more (see page 2057)
TObject Branch (see page 2058)	The *TObject* branch includes all VCL classes that descend from *TObject* but not from *TPersistent*. Much of the powerful capability of the component library is established by the methods that *TObject* introduces. *TObject* encapsulates the fundamental behavior common to all classes in the component library by introducing methods that provide: • The ability to respond when object instances are created or destroyed. • Class type and instance information on an object, and runtime type information (RTTI) about its published properties. • Support for handling messages (see page 1308) (VCL applications) . *TObject* is the immediate ancestor of many simple classes. Classes in the *TObject... more (see page 2058)*
TPersistent Branch (see page 2059)	The *TPersistent* branch includes all VCL classes that descend from *TPersistent* but not from *TComponent*. Persistence determines what gets saved with a form file or data module and what gets loaded into the form or data module when it is retrieved from memory. Because of their persistence, objects from this branch can appear at design time. However, they can't exist independently. Rather, they implement properties for components. Properties are only loaded and saved with a form if they have an owner. The owner must be some component. *TPersistent* introduces the *GetOwner* method, which lets the Form Designer determine the... more (see page 2059)
TComponent Branch (see page 2059)	The *TComponent* branch contains classes that descend from *TComponent* but not *TControl*. Objects in this branch are components that you can manipulate on forms at design time but which do not appear to the user at runtime. They are persistent objects that can do the following: • Appear on the **Tool palette** and be changed on the form. • Own and manage other components. • Load and save themselves. Several methods introduced by *TComponent* dictate how components act during design time and what information gets saved with the component. Streaming (the saving and loading of form files, which store information about the... more (see page 2059)

TControl Branch (see page 2060)	The *TControl* branch consists of components that descend from *TControl* but not *TWinControl* applications). Classes in this branch are controls: visual objects that the user can see and manipulate at runtime. All controls have properties, methods, and events in common that relate to how the control looks, such as its position, the cursor associated with the control's window, methods to paint or move the control, and events to respond to mouse actions. Controls in this branch, however, can never receive keyboard input. Whereas *TComponent* defines behavior for all components, *TControl* defines behavior for all visual controls.... more (see page 2060)
TWinControl/TWidgetControl Branch (see page 2061)	Most controls fall into the TWinControl/ *TWidgetControl* branch. Unlike graphic controls, controls in this branch have their own associated window or widget. Because of this, they are sometimes called windowed controls controls. Windowed controls all descend from *TWinControl*, which descends from the windows-only version of *TControl*. Controls in the *TWinControl*/*TWidgetControl* branch: • Can receive focus while an application is running, which means they can receive keyboard input from the application user. In comparison, graphic controls can only display data and respond to the mouse. • Can be the parent of one or more child controls. • Have a... more (see page 2061)

3.2.4.8.1 Understanding the Component Library

The component library is made up of objects that you can use in your projects. The VCL/RTL contains low-level classes and routines available for all VCL applications. VCL/RTL includes the runtime library (RTL) up to and including the Classes unit.

Use the VCL when you want to use native Windows controls, Windows-specific features, or extend an existing VCL application.

All classes in the VCL descend from *TObject*. *TObject* introduces methods that implement fundamental behavior like construction, destruction, and message handling.

Components are a subset of the component library that descend from the class *TComponent*. You can place components on a form or data module and manipulate them at design time. Using the **Object Inspector**, you can assign property values without writing code. Most components are either visual or nonvisual, depending on whether they are visible at runtime. Some components appear on the **Tool palette**.

Visual components, such as *TForm* and *TSpeedButton*, are called *controls* and descend from *TControl*. Controls are used in GUI applications, and appear to the user at runtime. *TControl* provides properties (see page 2056) that specify the visual attributes of controls, such as their height and width.

Nonvisual components are used for a variety of tasks. For example, if you are writing an application that connects to a database, you can place a *TDataSource* component on a form to connect a control and a dataset used by the control. This connection is not visible to the user, so *TDataSource* is nonvisual. At design time, nonvisual components are represented by an icon. This allows you to manipulate their properties and events just as you would a visual control.

Classes that are not components (that is, classes that descend from *TObject* but not *TComponent*) are also used for a variety of tasks. Typically, these classes are used for accessing system objects (such as a file or the clipboard) or for transient tasks (such as storing data in a list). You can't create instances of these classes at design time, although they are sometimes created by the components that you add in the Form Designer.

Detailed reference material on all VCL objects is accessible while you are programming. In the Code editor, place the cursor anywhere on the object and press F1 to display the Help topic. Objects, properties, methods, and events that are in the VCL are marked "VCL Reference."

Properties (see page 2056)

Objects (see page 2057)

3.2.4.8.2 Properties, Methods, and Events

The VCL hierarchy of classes is tied to the IDE, where you can develop applications quickly. The classes in the VCL are based on properties, methods, and events. Each class includes data members (properties), functions that operate on the data (methods), and a way to interact with users of the class (events). The VCL component library is written in the Delphi language, and it is based on the Windows API.

Properties

Properties are characteristics of an object that influence either the visible behavior or the operations of the object. For example, the *Visible* property determines whether an object can be seen in an application interface. Well-designed properties make your components easier for others to use and easier for you to maintain.

Here are some of the useful features of properties:

- Unlike methods, which are only available at runtime, you can see and change some properties at design time and get immediate feedback as the components change in the IDE.
- You can access some properties in the **Object Inspector**, where you can modify the values of your object visually. Setting properties at design time is easier than writing code and makes your code easier to maintain.
- Because the data is encapsulated, it is protected and private to the actual object.
- The calls to get and set the values of properties can be methods, so special processing can be done that is invisible to the user of the object. For example, data could reside in a table, but could appear as a normal data member to the programmer.
- You can implement logic that triggers events or modifies other data during the access of a property. For example, changing the value of one property may require you to modify another. You can change the methods created for the property.
- Properties can be virtual.
- A property is not restricted to a single object. Changing one property on one object can affect several objects. For example, setting the *Checked* property on a radio button affects all of the radio buttons in the group.

Methods

A *method* is a procedure that is always associated with a class. Methods define the behavior of an object. Class methods can access all the public (see page 2069) properties and fields of the class and are commonly referred to as member functions. Although most methods belong to an instance of a class, some methods belong instead to the class type. These are called class methods.

Events

An *event* is an action or occurrence detected by a program. Most modern applications are said to be event-driven, because they are designed to respond to events. In a program, the programmer has no way of predicting the exact sequence of actions a user will perform. For example, the user may choose a menu item, click a button, or mark some text. You can write code to handle the events in which you are interested, rather than writing code that always executes in the same restricted order.

Regardless of how an event is triggered, VCL objects look to see if you have written any code to handle that event. If you have, that code is executed; otherwise, the default event handling behavior takes place.

See Also

Types of Events (see page 2057)

Understanding the Component Library (see page 2055)

Objects (see page 2057)

3.2.4.8.3 Types of Events

The kinds of events that can occur can be divided into two main categories:

- User events
- System events
- Internal events

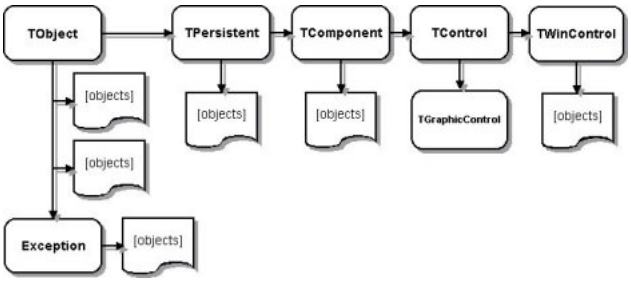
User events

User events are actions that the user initiates. Examples of user events are *OnClick* (the user clicked the mouse), *OnKeyPress* (the user pressed a key on the keyboard), and *OnDblClick* (the user double-clicked a mouse button).

System events

System events are events that the operating system fires for you. For example, the *OnTimer* event (which the Timer component issues whenever a predefined interval has elapsed), the *OnPaint* event (a component or window needs to be redrawn), and so on. Usually, system events are not directly initiated by a user action.

Internal events



Internal events are events that are generated by the objects in your application. An example of an internal event is the *OnPost* event that a dataset generates when your application tells it to post the current record.

Properties (see page 2056)

3.2.4.8.4 Objects, Components, and Controls

The following diagram is a greatly simplified view of the inheritance hierarchy that illustrates the relationship between objects, components, and controls.

Every object (class) inherits from *TObject*. Objects that can appear in the Form Designer inherit from *TPersistent* or *TComponent*. Controls, which appear to the user at runtime, inherit from *TControl*. There are two types of controls, graphic controls, which inherit from *TGraphicControl*, and windowed controls, which inherit from *TWinControl* or *TWidgetControl*. A control like *TCheckBox* inherits all the functionality of *TObject*, *TPersistent*, *TComponent*, *TControl*, and *TWinControl* or *TWidgetControl*, and adds specialized capabilities of its own.

The figure shows several important base classes, which are described in the following table:

Class	Description
TObject	Signifies the base class and ultimate ancestor of everything in the VCL *TObject* encapsulates the fundamental behavior common to all VCLobjects by introducing methods that perform basic functions such as creating, maintaining, and destroying an instance of an object.

Exception	Specifies the base class of all classes that relate to VCL exceptions. *Exception* provides a consistent interface for error conditions, and enables applications to handle error conditions gracefully.
TPersistent	Specifies the base class for all objects that implement publishable properties. Classes under *TPersistent* deal with sending data to streams and allow for the assignment of classes.
TComponent	Specifies the base class for all components. Components can be added to the **Tool palette** and manipulated at design time. Components can own other components.
TControl	Represents the base class for all controls that are visible at runtime. *TControl* is the common ancestor of all visual components and provides standard visual controls like position and cursor. This class also provides events that respond to mouse actions.
TWinControl or TWidgetControl	Specifies the base class of all controls that can have keyboard focus. Controls under *TWinControl* are called windowed controls while those under *TWidgetControl* are called widgets.

3.2.4.8.5 TObject Branch

The *TObject* branch includes all VCL classes that descend from *TObject* but not from *TPersistent*. Much of the powerful capability of the component library is established by the methods that *TObject* introduces. *TObject* encapsulates the fundamental behavior common to all classes in the component library by introducing methods that provide:

- The ability to respond when object instances are created or destroyed.
- Class type and instance information on an object, and runtime type information (RTTI) about its published properties.
- Support for handling messages (see page 1308) (VCL applications) .

TObject is the immediate ancestor of many simple classes. Classes in the *TObject* branch have one common, important characteristic: they are transitory. This means that these classes do not have a method to save the state that they are in prior to destruction; they are not persistent.

One of the main groups of classes in this branch is the *Exception* class. This class provides a large set of built-in exception classes for automatically handling divide-by-zero errors, file I/O errors, invalid typecasts, and many other exception conditions.

Another group in the *TObject* branch is classes that encapsulate data structures, such as:

- *TBits*, a class that stores an "array" of Boolean values.
- *TList*, a linked list class.
- *TStack*, a class that maintains a last-in first-out array of pointers.
- *TQueue*, a class that maintains a first-in first-out array of pointers.

Another group in the *TObject* branch are wrappers for external objects like *TPrinter*, which encapsulates a printer interface, and *TIniFile*, which lets a program read from or write to an ini file.

TStream is a good example of another type of class in this branch. *TStream* is the base class type for stream objects that can read from or write to various kinds of storage media, such as disk files, dynamic memory, and so on (see Using streams (see page 2099) for information on streams).

System::TObject

3.2.4.8.6 TPersistent Branch

The *TPersistent* branch includes all VCL classes that descend from *TPersistent* but not from *TComponent*. Persistence determines what gets saved with a form file or data module and what gets loaded into the form or data module when it is retrieved from memory.

Because of their persistence, objects from this branch can appear at design time. However, they can't exist independently. Rather, they implement properties for components. Properties are only loaded and saved with a form if they have an owner. The owner must be some component. *TPersistent* introduces the *GetOwner* method, which lets the Form Designer determine the owner of the object.

Classes in this branch are also the first to include a published section where properties can be automatically loaded and saved. A *DefineProperties* method lets each class indicate how to load and save properties.

Following are some of the classes in the *TPersistent* branch of the hierarchy:

- Graphics such as: *TBrush*, *TFont*, and *TPen*.
- Classes such as *TBitmap* and *TIcon*, which store and display visual images, and *TClipboard*, which contains text or graphics that have been cut or copied from an application.
- String lists, such as *TStringList*, which represent text or lists of strings that can be assigned at design time.
- Collections and collection items, which descend from *TCollection* or *TCollectionItem*. These classes maintain indexed collections of specially defined items that belong to a component. Examples include *THeaderSections* and *THeaderSection* or *TListColumns* and *TListColumn*.

TPersistent

3.2.4.8.7 TComponent Branch

The *TComponent* branch contains classes that descend from *TComponent* but not *TControl*. Objects in this branch are components that you can manipulate on forms at design time but which do not appear to the user at runtime. They are persistent objects that can do the following:

- Appear on the **Tool palette** and be changed on the form.

- Own and manage other components.
- Load and save themselves.

Several methods introduced by *TComponent* dictate how components act during design time and what information gets saved with the component. Streaming (the saving and loading of form files, which store information about the property values of objects on a form) is introduced in this branch. Properties are persistent if they are published and published properties are automatically streamed.

The *TComponent* branch also introduces the concept of ownership that is propagated throughout the component library. Two properties support ownership: *Owner* and *Components*. Every component has an *Owner* property that references another component as its owner. A component may own other components. In this case, all owned components are referenced in the component's *Components* property.

The constructor for every component takes a parameter that specifies the new component's owner. If the passed-in owner exists, the new component is added to that owner's Components list. Aside from using the Components list to reference owned components, this property also provides for the automatic destruction of owned components. As long as the component has an owner, it will be destroyed when the owner is destroyed. For example, since *TForm* is a descendant of *TComponent*, all components owned by a form are destroyed and their memory freed when the form is destroyed. (Assuming, of course, that the components have properly designed destructors that clean them up correctly.)

If a property type is a *TComponent* or a descendant, the streaming system creates an instance of that type when reading it in. If a property type is *TPersistent* but not *TComponent*, the streaming system uses the existing instance available through the property and reads values for that instance's properties.

Some of the classes in the *TComponent* branch include:

- *TActionList*, a class that maintains a list of actions, which provides an abstraction of the responses your program can make to user input.
- *TMainMenu*, a class that provides a menu bar and its accompanying drop-down menus for a form.
- *TOpenDialog*, TSaveDialog, TFontDialog, TFindDialog, TColorDialog, and so on, classes that display and gather information from commonly used dialog boxes.
- *TScreen*, a class that keeps track of the forms and data modules that an application creates, the active form, the active control within that form, the size and resolution of the screen, and the cursors and fonts available for the application to use.

Components that do not need a visual interface can be derived directly from *TComponent*. To make a tool such as a *TTimer* device, you can derive from *TComponent*. This type of component resides on the **Tool palette** but performs internal functions that are accessed through code rather than appearing in the user interface at runtime.

See Working with components for details on setting properties, calling methods, and working with events for components.

TWinControl/TWidgetControl Branch (see page 2061)

TComponent

3.2.4.8.8 TControl Branch

The *TControl* branch consists of components that descend from *TControl* but not *TWinControl* applications*)*. Classes in this branch are controls: visual objects that the user can see and manipulate at runtime. All controls have properties, methods, and events in common that relate to how the control looks, such as its position, the cursor associated with the control's window, methods to paint or move the control, and events to respond to mouse actions. Controls in this branch, however, can never receive keyboard input.

Whereas *TComponent* defines behavior for all components, *TControl* defines behavior for all visual controls. This includes drawing routines, standard events, and containership.

TControl introduces many visual properties that all controls inherit. These include the *Caption*, *Color*, *Font*, and *HelpContext* or *HelpKeyword*. While these properties inherited from *TControl*, they are only published—and hence appear in the **Object Inspector**—for controls to which they are applicable. For example, *TImage* does not publish the *Color* property, since its color is determined by the graphic it displays. *TControl* also introduces the *Parent* property, which specifies another control that visually contains the control.

Classes in the *TControl* branch often called graphic controls, because they all descend from *TGraphicControl*, which is an immediate descendant of *TControl*. Although these controls appear to the user at runtime, graphic controls do not have their own underlying window or widget. Instead, they use their parent's window or widget. It is because of this limitation that graphic controls cant receive keyboard input or act as a parent to other controls. However, because they do not have their own window or widget, graphic controls use fewer system resources. For details on many of the classes in the *TControl* branch, see graphics controls (see page 2040).

TControl is designed for VCL (Windows-only) applications. Many controls descend from *TControl*. The Windows-only controls use native Windows APIs in their implementations.

TControl

3.2.4.8.9 TWinControl/TWidgetControl Branch

Most controls fall into the TWinControl/ *TWidgetControl* branch. Unlike graphic controls, controls in this branch have their own associated window or widget. Because of this, they are sometimes called windowed controls controls. Windowed controls all descend from *TWinControl*, which descends from the windows-only version of *TControl*.

Controls in the *TWinControl*/*TWidgetControl* branch:

- Can receive focus while an application is running, which means they can receive keyboard input from the application user. In comparison, graphic controls can only display data and respond to the mouse.
- Can be the parent of one or more child controls.
- Have a handle, or unique identifier, that allows them to access the underlying window or widget.

The *TWinControl/TWidgetControl* branch includes both controls that are drawn automatically (such as *TEdit*, *TListBox*, *TComboBox*, *TPageControl*, and so on) and custom controls that do not correspond directly to a single underlying Windows control or widget. Controls in this latter category, which includes classes like *TStringGrid* and *TDBNavigator*, must handle the details of painting themselves. Because of this, they descend from *TCustomControl*, which introduces a *Canvas* property on which they can paint themselves.

System::TObject

3.2.4.9 Using the object model

Topics

Name	Description
Using Object Variables (see page 2064)	You can assign one object variable to another object variable if the variables are of the same type or are assignment compatible. In particular, you can assign an object variable to another object variable if the type of the variable to which you are assigning is an ancestor of the type of the variable being assigned. For example, here is a *TSimpleForm* type declaration and a variable declaration section declaring two variables, *AForm* and *Simple*:
Changing the Name of a Component (see page 2065)	You should always use the **Object Inspector** to change the name of a component. For example, suppose you want to change a form's name from the default *Form1* to a more descriptive name, such as *ColorWindow*. When you change the form's *Name* property in the **Object Inspector**, the new name is automatically reflected in the form's .dfm or .xfm file (which you usually don't edit manually) and in the source code that the IDE generates:
Components and Ownership (see page 2066)	Delphi components have a built-in memory-management mechanism that allows one component to assume responsibility for freeing another. The former component is said to *own* the latter. The memory for an owned component is automatically freed when its owner's memory is freed. The owner of a component—the value of its *Owner* property—is determined by a parameter passed to the constructor when the component is created. By default, a form owns all components on it and is in turn owned by the application. Thus, when the application shuts down, the memory for all forms and the components on them is freed. Ownership... more (see page 2066)
Creating, Instantiating, and Destroying Objects (see page 2066)	Many of the objects you use in the Form Designer, such as buttons and edit boxes, are visible at both design time and runtime. Some, such as common dialog boxes, appear only at runtime. Still others, such as timers and data source components, have no visual representation at runtime. You may want to create your own classes. For example, you could create a *TEmployee* class that contains *Name*, *Title*, and *HourlyPayRate* properties. You could then add a *CalculatePay* method that uses the data in *HourlyPayRate* to compute a paycheck amount. The *TEmployee* type declaration might look like this:... more (see page 2066)
Examining a Delphi Object (see page 2067)	When you create a new project, the IDE displays a new form for you to customize. In the Code editor, the automatically generated unit declares a new class type for the form and includes the code that creates the new form instance. The generated code for a new Windows application looks like this:
Inheriting Data and Code from an Object (see page 2069)	The *TForm1* object in examining a Delphi object (see page 2067) seems simple. *TForm1* appears to contain one field (*Button1*), one method (*Button1Click*), and no properties. Yet you can show, hide, or resize of the form, add or delete standard border icons, and set up the form to become part of a Multiple Document Interface (MDI) application. You can do these things because the form has *inherited* all the properties and methods of the component *TForm*. When you add a new form to your project, you start with TForm and customize it by adding components, changing property values,... more (see page 2069)
Private, Protected, Public, and Published Declarations (see page 2069)	A class type declaration contains three or four possible sections that control the accessibility of its fields and methods:
Scope and Qualifiers (see page 2070)	*Scope* determines the accessibility of an object's fields, properties, and methods. All members declared in a class are available to that class and, as is discussed later, often to its descendants. Although a method's implementation code appears outside of the class declaration, the method is still within the scope of the class because it is declared in the class declaration. When you write code to implement a method that refers to properties, methods, or fields of the class where the method is declared, you don't need to preface those identifiers with the name of the class. For example, if you... more (see page 2070)

Using the Object Model (see page 2071)	The Delphi language is a set of object-oriented extensions to standard Pascal. Object-oriented programming is an extension of structured programming that emphasizes code reuse and encapsulation of data with functionality. Once you define a class, you and other programmers can use it in different applications, thus reducing development time and increasing productivity. The following topics provide a brief introduction to object-oriented concepts for programmers who are just starting out with the Delphi language. For more details on object-oriented programming for programmers who want to write components that can be installed on the **Tool palette**, see Overview of Component Creation (see page 1313)... more (see page 2071)
What Is an Object? (see page 2071)	A *class* is a data type that encapsulates *data* and *operations on data* in a single unit. Before object-oriented programming, data and operations (functions) were treated as separate elements. An *object* is an instance of a class. That is, it is a value whose type is a class. The term object is often used more loosely in this documentation and where the distinction between a class and an instance of the class is not important, the term "object" may also refer to a class. You can begin to understand objects if you understand Pascal records or *structures* in C. Records... more (see page 2071)
TInterfacedObject (see page 2072)	When defining a class that supports one or more interfaces, it is convenient to use *TInterfacedObject* as a base class because it implements the methods of *IInterface*. *TInterfacedObject* class is declared in the *System* unit as follows:
Defining New Classes (Delphi) (see page 2072)	Although there are many classes in the object hierarchy, you are likely to need to create additional classes if you are writing object-oriented programs. The classes you write must descend from *TObject* or one of its descendants. The advantage of using classes comes from being able to create new classes as descendants of existing ones. Each descendant class inherits the fields and methods of its parent and ancestor classes. You can also declare methods in the new class that override inherited ones, introducing new, more specialized behavior. The general syntax of a descendant class is as follows:
Aggregation (see page 2074)	Aggregation offers a modular approach to code reuse through sub-objects that make up the functionality of a containing object, but that hide the implementation details from that object. In aggregation, an outer object implements one or more interfaces. At a minimum, it must implement *IInterface*. The inner object, or objects, also implement one or more interfaces. However, only the outer object exposes the interfaces. That is, the outer object exposes both the interfaces it implements and the ones that its contained objects implement. Clients know nothing about inner objects. While the outer object provides access to the inner object... more (see page 2074)
Implementing IInterface (see page 2075)	Just as all objects descend, directly or indirectly, from *TObject*, all interfaces derive from the *IInterface* interface. IInterface provides for dynamic querying and lifetime management of the interface. This is established in the three *IInterface* methods: • *QueryInterface* dynamically queries a given object to obtain interface references for the interfaces that the object supports. • *_AddRef* is a reference counting method that increments the count each time a call to QueryInterface succeeds. While the reference count is nonzero the object must remain in memory. • *_Release* is used with _AddRef to allow an object to track its own lifetime and determine when... more (see page 2075)
Memory Management of Interface Objects (see page 2075)	One of the concepts behind the design of interfaces is ensuring the lifetime management of the objects that implement them. The *_AddRef* and *_Release* methods of *IInterface* provide a way to implement this lifetime management. *_AddRef* and *_Release* track the lifetime of an object by incrementing the reference count on the object when an interface reference is passed to a client, and will destroy the object when that reference count is zero. If you are creating COM objects for distributed applications (in the Windows environment only), then you should strictly adhere to the reference counting rules. However, if you are... more (see page 2075)

Not Using Reference Counting (see page 2076)	If your object is a component or a control that is owned by another component, then it is part of a different memory management system that is based in *TComponent*. Although some classes mix the object lifetime management approaches of *TComponent* and interface reference counting, this is very tricky to implement correctly. To create a component that supports interfaces but bypasses the interface reference counting mechanism, you must implement the *_AddRef* and *_Release* methods in code such as the following:
Reusing Code and Delegation (see page 2076)	One approach to reusing code with interfaces is to have one interfaced object contain, or be contained by another. Using properties that are object types provides an approach to containment and code reuse. To support this design for interfaces, the Delphi language has a keyword implements, that makes if easy to write code to delegate (see page 2078) all or part of the implementation of an interface to a subobject. Aggregation (see page 2074) is another way of reusing code through containment and delegation. In aggregation, an outer object uses an inner object that implements interfaces which are exposed only by the outer object.
Using Interfaces Across the Hierarchy (see page 2077)	Using interfaces lets you separate the way a class is used from the way it is implemented. Two classes can implement the same interface without descending from the same base class. By obtaining an interface from either class, you can call the same methods without having to know the type of the class. This polymorphic use of the same methods on unrelated objects is possible because the objects implement the same interface. For example, consider the interface,
Using Implements for Delegation (see page 2078)	Many classes have properties that are subobjects. You can also use interfaces as property types. When a property is of an interface type (or a class type that implements the methods of an interface) you can use the keyword implements to specify that the methods of that interface are delegated to the object or interface reference which is the value of the property. The delegate only needs to provide implementation for the methods. It does not have to declare the interface support. The class containing the property must include the interface in its ancestor list. By default, using the implements... more (see page 2078)
Using Interfaces (see page 2079)	Delphi is a single-inheritance language. That means that any class has only a single direct ancestor. However, there are times you want a new class to inherit properties and methods from more than one base class so that you can use it sometimes like one and sometimes like the other. Interfaces let you achieve something like this effect. An interface is like a class that contains only abstract methods (methods with no implementation) and a clear definition of their functionality. Interface method definitions include the number and types of their parameters, their return type, and their expected behavior. By convention,... more (see page 2079)
Using Interfaces in Distributed Applications (see page 2079)	In VCL applications, interfaces are a fundamental element in the COM and SOAP distributed object models. Delphi provides base classes for these technologies that extend the basic interface functionality in *TInterfacedObject*, which simply implements the *IInterface* interface methods. When using COM, classes and interfaces are defined in terms of *IUnknown* rather than *IInterface*. There is no semantic difference between *IUnknown* and *IInterface*, the use of *IUnknown* is simply a way to adapt Delphi interfaces to the COM definition. COM classes add functionality for using class factories and class identifiers (CLSIDs). Class factories are responsible for creating class... more (see page 2079)
Using Interfaces with Procedures (see page 2080)	Interfaces allow you to write generic procedures that can handle objects without requiring that the objects descend from a particular base class. Using the *IPaint* and *IRotate* interfaces defined previously, you can write the following procedures:
Using Reference Counting (see page 2081)	The Delphi compiler provides most of the *IInterface* memory management for you by its implementation of interface querying and reference counting. Therefore, if you have an object that lives and dies by its interfaces, you can easily use reference counting by deriving from *TInterfacedObject*. If you decide to use reference counting, then you must be careful to only hold the object as an interface reference, and to be consistent in your reference counting. For example:
Using the as Operator with Interfaces (see page 2082)	Classes that implement interfaces can use the as operator for dynamic binding on the interface. In the following example,

3.2.4.9.1 Using Object Variables

You can assign one object variable to another object variable if the variables are of the same type or are assignment compatible. In particular, you can assign an object variable to another object variable if the type of the variable to which you are assigning is an ancestor of the type of the variable being assigned. For example, here is a *TSimpleForm* type declaration and a variable

declaration section declaring two variables, *AForm* and *Simple*:

```
type
  TSimpleForm = class(TForm)
    Button1: TButton;
    Edit1: TEdit;
  private
    { Private declarations }
  public
    { Public declarations }
  end;
var
  AForm: TForm;
  SimpleForm: TSimpleForm;
```

AForm is of type *TForm*, and *SimpleForm* is of type *TSimpleForm*. Because *TSimpleForm* is a descendant of *TForm*, this assignment statement is legal:

```
AForm := SimpleForm;
```

Suppose you write an event handler for the *OnClick* event of a button. When the button is clicked, the event handler for the *OnClick* event is called. Each event handler has a *Sender* parameter of type *TObject*:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
.
.
.
end;
```

Because *Sender* is of type *TObject*, any object can be assigned to *Sender*. The value of *Sender* is always the control or component that responds to the event. You can test *Sender* to find the type of component or control that called the event handler using the reserved word is. For example,

```
if Sender is TEdit then
  DoSomething
else
  DoSomethingElse;
```

Scope and Qualifiers (see page 2070)

Creating (see page 2066)

3.2.4.9.2 Changing the Name of a Component

You should always use the **Object Inspector** to change the name of a component. For example, suppose you want to change a form's name from the default *Form1* to a more descriptive name, such as *ColorWindow*. When you change the form's *Name* property in the **Object Inspector**, the new name is automatically reflected in the form's .dfm or .xfm file (which you usually don't edit manually) and in the source code that the IDE generates:

```
unit Unit1;
interface
uses Windows, Messages, SysUtils, Variants, Classes, Graphics, Controls, Forms, Dialogs;
type
  TColorWindow = class(TForm){ Changed from TForm1 to TColorWindow }
    Button1: TButton;
    procedure Button1Click(Sender: TObject);
  private
    { Private declarations }
  public
    { Public declarations }
```

```
  end;
var
  ColorWindow: TColorWindow;{ Changed from Form1 to ColorWindow }
implementation
{$R *.dfm}
procedure TColorWindow.Button1Click(Sender: TObject);
begin
  Form1.Color := clGreen;{ The reference to Form1 didn"t change! }
end;
end.
```

Note that the code in the *OnClick* event handler for the button hasn't changed. Because you wrote the code, you have to update it yourself and correct any references to the form:

```
procedure TColorWindow.Button1Click(Sender: TObject);
begin
  ColorWindow.Color := clGreen;
end;
```

3.2.4.9.3 Components and Ownership

Delphi components have a built-in memory-management mechanism that allows one component to assume responsibility for freeing another. The former component is said to *own* the latter. The memory for an owned component is automatically freed when its owner's memory is freed. The owner of a component—the value of its *Owner* property—is determined by a parameter passed to the constructor when the component is created. By default, a form owns all components on it and is in turn owned by the application. Thus, when the application shuts down, the memory for all forms and the components on them is freed.

Ownership applies only to *TComponent* and its descendants. If you create, for example, a *TStringList* or *TCollection* object (even if it is associated with a form), you are responsible for freeing the object.

Creating (see page 2066)

Memory Management of Interface Objects (see page 2075)

3.2.4.9.4 Creating, Instantiating, and Destroying Objects

Many of the objects you use in the Form Designer, such as buttons and edit boxes, are visible at both design time and runtime. Some, such as common dialog boxes, appear only at runtime. Still others, such as timers and data source components, have no visual representation at runtime.

You may want to create your own classes. For example, you could create a *TEmployee* class that contains *Name*, *Title*, and *HourlyPayRate* properties. You could then add a *CalculatePay* method that uses the data in *HourlyPayRate* to compute a paycheck amount. The *TEmployee* type declaration might look like this:

```
type
  TEmployee = class(TObject)
  private
    FName: string;
    FTitle: string;
    FHourlyPayRate: Double;
  public
    property Name: string read FName write FName;
    property Title: string read FTitle write FTitle;
    property HourlyPayRate: Double read FHourlyPayRate write FHourlyPayRate;
```

```
    function CalculatePay: Double;
  end;
```

In addition to the fields, properties, and methods you've defined, *TEmployee* inherits all the methods of *TObject*. You can place a type declaration like this one in either the interface or implementation part of a unit, and then create instances of the new class by calling the *Create* method that *TEmployee* inherits from *TObject*:

```
var
  Employee: TEmployee;
begin
  Employee := TEmployee.Create;
end;
```

The *Create* method is called a *constructor*. It allocates memory for a new instance object and returns a reference to the object.

Components on a form are created and destroyed automatically. However, if you write your own code to instantiate objects, you are responsible for disposing of them as well. Every object inherits a *Destroy* method (called a *destructor*) from *TObject*. To destroy an object, however, you should call the *Free* method (also inherited from *TObject*), because *Free* checks for a nil reference before calling *Destroy*. For example,

```
Employee.Free;
```

destroys the *Employee* object and deallocates its memory.

Using Object Variables (see page 2064)

3.2.4.9.5 Examining a Delphi Object

When you create a new project, the IDE displays a new form for you to customize. In the Code editor, the automatically generated unit declares a new class type for the form and includes the code that creates the new form instance. The generated code for a new Windows application looks like this:

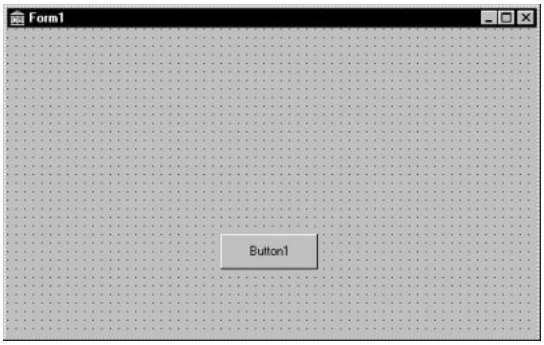
```
unit Unit1;
interface
uses Windows, Messages, SysUtils, Variants, Classes, Graphics, Controls, Forms, Dialogs;
type
TForm1 = class(TForm){ The type declaration of the form begins here }
  private
    { Private declarations }
  public
    { Public declarations }
  end;{ The type declaration of the form ends here }
var
  Form1: TForm1;
implementation{ Beginning of implementation part }
{$R *.dfm}
end.{ End of implementation part and unit}
```

The new class type is *TForm1*, and it is derived from type *TForm*, which is also a class.

A class is like a record in that they both contain data fields, but a class also contains methods—code that acts on the object's data. So far, *TForm1* appears to contain no fields or methods, because you haven't added any components (the fields of the new object) to the form and you haven't created any event handlers (the methods of the new object). *TForm1* does contain inherited fields and methods, even though you don't see them in the type declaration.

This variable declaration declares a variable named *Form1* of the new type *TForm1*.

```
var
```



```
  Form1: TForm1;
```

Form1 represents an instance, or object, of the class type *TForm1*. You can declare more than one instance of a class type; you might want to do this, for example, to create multiple child windows in a Multiple Document Interface (MDI) application. Each instance maintains its own data, but all instances use the same code to execute methods.

Although you haven't added any components to the form or written any code, you already have a complete GUI application that you can compile and run. All it does is display a blank form.

Suppose you add a button component to this form and write an *OnClick* event handler that changes the color of the form when the user clicks the button. The result might look like this:

A simple form

When the user clicks the button, the form's color changes to green. This is the event-handler code for the button's *OnClick* event:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  Form1.Color := clGreen;
end;
```

Objects can contain other objects as data fields. Each time you place a component on a form, a new field appears in the form's type declaration. If you create the application described above and look at the code in the Code editor, this is what you see:

```
unit Unit1;
interface
uses Windows, Messages, SysUtils, Variants, Classes, Graphics, Controls, Forms, Dialogs;
type
  TForm1 = class(TForm)
    Button1: TButton;{ New data field }
    procedure Button1Click(Sender: TObject);{ New method declaration }
  private
    { Private declarations }
  public
    { Public declarations }
  end;
var
  Form1: TForm1;
implementation
{$R *.dfm}
procedure TForm1.Button1Click(Sender: TObject);{ The code of the new method }
begin
  Form1.Color := clGreen;
end;
end.
```

TForm1 has a *Button1* field that corresponds to the button you added to the form. *TButton* is a class type, so *Button1* refers to an object.

All the event handlers you write using the IDE are methods of the form object. Each time you create an event handler, a method is declared in the form object type. The *TForm1* type now contains a new method, the *Button1Click* procedure, declared in the *TForm1* type declaration. The code that implements the *Button1Click* method appears in the implementation part of the unit.

3.2.4.9.6 Inheriting Data and Code from an Object

The *TForm1* object in examining a Delphi object (see page 2067) seems simple. *TForm1* appears to contain one field (*Button1*), one method (*Button1Click*), and no properties. Yet you can show, hide, or resize of the form, add or delete standard border icons, and set up the form to become part of a Multiple Document Interface (MDI) application. You can do these things because the form has *inherited* all the properties and methods of the component *TForm*. When you add a new form to your project, you start with TForm and customize it by adding components, changing property values, and writing event handlers. To customize any object, you first derive a new object from the existing one; when you add a new form to your project, the IDE automatically derives a new form from the *TForm* type:

```
TForm1 = class(TForm)
```

A derived class inherits all the properties, events, and methods of the class from which it derives. The derived class is called a *descendant* and the class from which it derives is called an *ancestor*. If you look up *TForm* in the online Help, you'll see lists of its properties, events, and methods, including the ones that *TForm* inherits from *its* ancestors. A Delphi class can have only one immediate ancestor, but it can have many direct descendants.

3.2.4.9.7 Private, Protected, Public, and Published Declarations

A class type declaration contains three or four possible sections that control the accessibility of its fields and methods:

```
Type
  TClassName = Class(TObject)
    public
      {public fields}
      {public methods}
    protected
      {protected fields}
      {protected methods}
    private
      {private fields}
      {private methods}
end;
```

- The public section declares fields and methods with no access restrictions. Class instances and descendant classes can access these fields and methods. A public member is accessible from wherever the class it belongs to is accessible—that is, from the unit where the class is declared and from any unit that uses that unit.
- The protected section includes fields and methods with some access restrictions. A protected member is accessible within the unit where its class is declared and by any descendant class, regardless of the descendant class's unit.
- The private section declares fields and methods that have rigorous access restrictions. A private member is accessible only within the unit where it is declared. Private members are often used in a class to implement other (public or published)

methods and properties.

- For classes that descend from *TPersistent*, a published section declares properties and events that are available at design time. A published member has the same visibility as a public member, but the compiler generates runtime type information for published members. Published properties appear in the **Object Inspector** at design time.

When you declare a field, property, or method, the new member is added to one of these four sections, which gives it its *visibility*: private, protected, public, or published.

Properties (see page 2056)

Scope and Qualifiers (see page 2070)

Defining New Classes (see page 2072)

3.2.4.9.8 Scope and Qualifiers

Scope determines the accessibility of an object's fields, properties, and methods. All members declared in a class are available to that class and, as is discussed later, often to its descendants. Although a method's implementation code appears outside of the class declaration, the method is still within the scope of the class because it is declared in the class declaration.

When you write code to implement a method that refers to properties, methods, or fields of the class where the method is declared, you don't need to preface those identifiers with the name of the class. For example, if you put a button on a new form, you could write this event handler for the button's *OnClick* event:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  Color := clFuchsia;
  Button1.Color := clLime;
end;
```

The first statement is equivalent to

```
Form1.Color := clFuchsia
```

You don't need to qualify *Color* with *Form1* because the *Button1Click* method is part of *TForm1*; identifiers in the method body therefore fall within the scope of the *TForm1* instance where the method is called. The second statement, in contrast, refers to the color of the button object (not of the form where the event handler is declared), so it requires qualification.

The IDE creates a separate unit (source code) file for each form. If you want to access one form's components from another form's unit file, you need to qualify the component names, like this:

```
Form2.Edit1.Color := clLime;
```

In the same way, you can access a component's methods from another form. For example,

```
Form2.Edit1.Clear;
```

To access *Form2*'s components from *Form1*'s unit file, you must also add *Form2*'s unit to the uses clause of *Form1*'s unit.

The scope of a class extends to its descendants. You can, however, redeclare a field, property, or method in a descendant class. Such redeclarations either hide or override the inherited member.

Private (see page 2069)

3.2.4.9.9 Using the Object Model

The Delphi language is a set of object-oriented extensions to standard Pascal. Object-oriented programming is an extension of structured programming that emphasizes code reuse and encapsulation of data with functionality. Once you define a class, you and other programmers can use it in different applications, thus reducing development time and increasing productivity.

The following topics provide a brief introduction to object-oriented concepts for programmers who are just starting out with the Delphi language. For more details on object-oriented programming for programmers who want to write components that can be installed on the **Tool palette**, see Overview of Component Creation (see page 1313).

- What is an object? (see page 2071)
- Inheriting data and code from an object (see page 2069)
- Scope and qualifiers (see page 2070)
- Using object variables (see page 2064)
- Creating (see page 2066)
- Defining new classes (see page 2072)
- Using interfaces (see page 2079)

Overview of Component Creation (see page 1313)

Understanding the Class Libraries (see page 2072)

3.2.4.9.10 What Is an Object?

A *class* is a data type that encapsulates *data* and *operations on data* in a single unit. Before object-oriented programming, data and operations (functions) were treated as separate elements. An *object* is an instance of a class. That is, it is a value whose type is a class. The term object is often used more loosely in this documentation and where the distinction between a class and an instance of the class is not important, the term "object" may also refer to a class.

You can begin to understand objects if you understand Pascal records or *structures* in C. Records are made of up fields that contain data, where each field has its own type. Records make it easy to refer to a collection of varied data elements.

Objects are also collections of data elements. But objects—unlike records—contain procedures and functions that operate on their data. These procedures and functions are called *methods*.

An object's data elements are accessed through *properties*. The properties of many Delphi objects have values that you can change at design time without writing code. If you want a property value to change at runtime, you need to write only a small amount of code.

The combination of data and functionality in a single unit is called *encapsulation*. In addition to encapsulation, object-oriented programming is characterized by *inheritance* and *polymorphism*. Inheritance means that objects derive functionality from other objects (called *ancestors*); objects can modify their inherited behavior. Polymorphism means that different objects derived from the same ancestor support the same method and property interfaces, which often can be called interchangeably.

Understanding the Class Libraries (see page 2072)

Inheriting Data and Code from an Object (see page 2069)

Scope and Qualifiers (see page 2070)

Using Object Variables (see page 2064)

Creating (see page 2066)

Defining New Classes (see page 2072)

Using Interfaces (see page 2079)

3.2.4.9.11 TInterfacedObject

When defining a class that supports one or more interfaces, it is convenient to use *TInterfacedObject* as a base class because it implements the methods of *IInterface*. *TInterfacedObject* class is declared in the *System* unit as follows:

```
type
  TInterfacedObject = class(TObject, IInterface)
  protected
    FRefCount: Integer;
    function QueryInterface(const IID: TGUID; out Obj): HResult; stdcall;
    function _AddRef: Integer; stdcall;
    function _Release: Integer; stdcall;
  public
    procedure AfterConstruction; override;
procedure BeforeDestruction; override;
class function NewInstance: TObject; override;
    property RefCount: Integer read FRefCount;
  end;
```

Deriving directly from *TInterfacedObject* is straightforward. In the following example declaration, *TDerived* is a direct descendant of *TInterfacedObject* and implements a hypothetical *IPaint* interface.

```
type
  TDerived = class(TInterfacedObject, IPaint)
  .
  .
  .
  end;
```

Because it implements the methods of *IInterface*, *TInterfacedObject* automatically handles reference counting and memory management of interfaced objects. For more information, see Memory management of interface objects (see page 2075), which also discusses writing your own classes that implement interfaces but that do not follow the reference-counting mechanism inherent in *TInterfacedObject*.

See Also

Using Interfaces Across the Hierarchy (see page 2077)

Using Interfaces with Procedures (see page 2080)

Implementing IInterface (see page 2075)

Memory Management of Interface Objects (see page 2075)

3.2.4.9.12 Defining New Classes (Delphi)

Although there are many classes in the object hierarchy, you are likely to need to create additional classes if you are writing object-oriented programs. The classes you write must descend from *TObject* or one of its descendants.

The advantage of using classes comes from being able to create new classes as descendants of existing ones. Each descendant class inherits the fields and methods of its parent and ancestor classes. You can also declare methods in the new class that override inherited ones, introducing new, more specialized behavior.

The general syntax of a descendant class is as follows:

```
Type
  TClassName = Class (TParentClass)
    public
      {public fields}
      {public methods}
    protected
      {protected fields}
      {protected methods}
    private
      {private fields}
      {private methods}
end;
```

If no parent class name is specified, the class inherits directly from *TObject*. *TObject* defines only a handful of methods, including a basic constructor and destructor.

To define a class:

1. In the IDE, start with a project open and choose **File** ▶ **New** ▶ **Unit** to create a new unit where you can define the new class.
2. Add the uses clause and type section to the interface section.
3. In the type section, write the class declaration. You need to declare all the member variables, properties, methods, and events.

```
TMyClass = class; {This implicitly descends from TObject}
public
.
.
.
private
.
.
.
published {If descended from TPersistent or below}
.
.
.
```

If you want the class to descend from a specific class, you need to indicate that class in the definition:

```
TMyClass = class(TParentClass); {This descends from TParentClass}
```

For example:

```
type TMyButton = class(TButton)
  property Size: Integer;
  procedure DoSomething;
end;
```

4. Some editions of the IDE include a feature called class completion that simplifies the work of defining and implementing new classes by generating skeleton code for the class members you declare. If you have code completion, invoke it to finish the class declaration: place the cursor within a method definition in the interface section and press `Ctrl+Shift+C` (or right-click and select Complete Class at Cursor). Any unfinished property declarations are completed, and for any methods that require an implementation, empty methods are added to the implementation section. If you do not have class completion, you need to write the code yourself, completing property declarations and writing the methods. Given the example above, if you have class completion, read and write specifiers are added to your declaration, including any supporting fields or methods:

```
type TMyButton = class(TButton)
  property Size: Integer read FSize write SetSize;
  procedure DoSomething;
private
  FSize: Integer;
  procedure SetSize(const Value: Integer);
```

The following code is also added to the implementation section of the unit.

```
{ TMyButton }
procedure TMyButton.DoSomething;
```

```
begin
end;
procedure TMyButton.SetSize(const Value: Integer);
begin
FSize := Value;
end;
```

5. Fill in the methods. For example, to make it so the button beeps when you call the *DoSomething* method, add the Beep between begin and end.

```
{ TMyButton }
procedure TMyButton.DoSomething;
begin
  Beep;
end;
procedure TMyButton.SetSize(const Value: Integer);
begin
  if fsize < > value then
  begin
    FSize := Value;
    DoSomething;
  end;
end;
```

Note that the button also beeps when you call *SetSize* to change the size of the button.

Creating (see page 2066)

Using Interfaces (see page 2079)

3.2.4.9.13 Aggregation

Aggregation offers a modular approach to code reuse through sub-objects that make up the functionality of a containing object, but that hide the implementation details from that object. In aggregation, an outer object implements one or more interfaces. At a minimum, it must implement *IInterface*. The inner object, or objects, also implement one or more interfaces. However, only the outer object exposes the interfaces. That is, the outer object exposes both the interfaces it implements and the ones that its contained objects implement.

Clients know nothing about inner objects. While the outer object provides access to the inner object interfaces, their implementation is completely transparent. Therefore, the outer object class can exchange the inner object class type for any class that implements the same interface. Correspondingly, the code for the inner object classes can be shared by other classes that want to use it.

The aggregation model defines explicit rules for implementing *IInterface* using delegation. The inner object must implement two versions of the *IInterface* methods.

- It must implement *IInterface* on itself, controlling its own reference count. This implementation of *IInterface* tracks the relationship between the outer and the inner object. For example, when an object of its type (the inner object) is created, the creation succeeds only for a requested interface of type *IInterface*.
- It also implements a second *IInterface* for all the interfaces it implements that the outer object exposes. This second *IInterface* delegates calls to *QueryInterface*, *_AddRef*, and *_Release* to the outer object. The outer *IInterface* is referred to as the "controlling Unknown."

Refer to the MS online help for the rules about creating an aggregation. When writing your own aggregation classes, you can also refer to the implementation details of *IInterface* in *TComObject*. *TComObject* is a COM class that supports aggregation. If

you are writing COM applications, you can also use *TComObject* directly as a base class.

See Also

Using Implements for Delegation (see page 2078)

Implementing IInterface (see page 2075)

3.2.4.9.14 Implementing IInterface

Just as all objects descend, directly or indirectly, from *TObject*, all interfaces derive from the *IInterface* interface. IInterface provides for dynamic querying and lifetime management of the interface. This is established in the three *IInterface* methods:

- *QueryInterface* dynamically queries a given object to obtain interface references for the interfaces that the object supports.
- *_AddRef* is a reference counting method that increments the count each time a call to QueryInterface succeeds. While the reference count is nonzero the object must remain in memory.
- *_Release* is used with _AddRef to allow an object to track its own lifetime and determine when it is safe to delete itself. Once the reference count reaches zero, the object is freed from memory. Every class that implements interfaces must implement the three IInterface methods, as well as all of the methods declared by any other ancestor interfaces, and all of the methods declared by the interface itself. You can, however, inherit the implementations of methods of interfaces declared in your class.

By implementing these methods yourself, you can provide an alternative means of lifetime management, disabling reference-counting. This is a powerful technique that lets you decouple interfaces from reference-counting.

Using the as Operator with Interfaces (see page 2082)

Reusing Code and Delegation (see page 2076)

Memory Management of Interface Objects (see page 2075)

Using Interfaces in Distributed Applications (see page 2079)

3.2.4.9.15 Memory Management of Interface Objects

One of the concepts behind the design of interfaces is ensuring the lifetime management of the objects that implement them. The *_AddRef* and *_Release* methods of *IInterface* provide a way to implement this lifetime management. *_AddRef* and *_Release* track the lifetime of an object by incrementing the reference count on the object when an interface reference is passed to a client, and will destroy the object when that reference count is zero.

If you are creating COM objects for distributed applications (in the Windows environment only), then you should strictly adhere to the reference counting rules. However, if you are using interfaces only internally in your application, then you have a choice that depends upon the nature of your object and how you decide to use it.

Using the as Operator with Interfaces (see page 2082)

Reusing Code and Delegation (see page 2076)

Using Interfaces Across the Hierarchy (see page 2077)

Using Interfaces in Distributed Applications (see page 2079)

3.2.4.9.16 Not Using Reference Counting

If your object is a component or a control that is owned by another component, then it is part of a different memory management system that is based in *TComponent*. Although some classes mix the object lifetime management approaches of *TComponent* and interface reference counting, this is very tricky to implement correctly.

To create a component that supports interfaces but bypasses the interface reference counting mechanism, you must implement the *_AddRef* and *_Release* methods in code such as the following:

```
function TMyObject._AddRef: Integer;
begin
  Result := -1;
end;
function TMyObject._Release: Integer;
begin
  Result := -1;
end;
```

You would still implement *QueryInterface* as usual to provide dynamic querying on your object.

Note that, because you implement *QueryInterface*, you can still use the as operator for interfaces, as long as you create an interface identifier (IID). You can also use aggregation. If the outer object is a component, the inner object implements reference counting as usual, by delegating to the "controlling Unknown." It is at the level of the outer object that the decision is made to circumvent the *_AddRef* and *_Release* methods, and to handle memory management via another approach. In fact, you can use *TInterfacedObject* as a base class for an inner object of an aggregation that has a as its containing outer object one that does not follow the interface lifetime model.

Note: The "controlling Unknown" is the *IUnknown* implemented by the outer object and the one for which the reference count of the entire object is maintained. *IUnknown* is the same as *IInterface*, but is used instead in COM-based applications (Windows only). For more information distinguishing the various implementations of the *IUnknown* or *IInterface* interface by the inner and outer objects, see Aggregation (see page 2074) and the Microsoft online Help topics on the "controlling Unknown."

Using Reference Counting (see page 2081)

3.2.4.9.17 Reusing Code and Delegation

One approach to reusing code with interfaces is to have one interfaced object contain, or be contained by another. Using properties that are object types provides an approach to containment and code reuse. To support this design for interfaces, the Delphi language has a keyword implements, that makes if easy to write code to delegate (see page 2078) all or part of the implementation of an interface to a subobject.

Aggregation (see page 2074) is another way of reusing code through containment and delegation. In aggregation, an outer object uses an inner object that implements interfaces which are exposed only by the outer object.

Memory Management of Interface Objects (see page 2075)

Using Interfaces in Distributed Applications (see page 2079)

3.2.4.9.18 Using Interfaces Across the Hierarchy

Using interfaces lets you separate the way a class is used from the way it is implemented. Two classes can implement the same interface without descending from the same base class. By obtaining an interface from either class, you can call the same methods without having to know the type of the class. This polymorphic use of the same methods on unrelated objects is possible because the objects implement the same interface. For example, consider the interface,

```
IPaint = interface
  procedure Paint;
end;
```

and the two classes,

```
TSquare = class(TPolygonObject, IPaint)
  procedure Paint;
end;
TCircle = class(TCustomShape, IPaint)
  procedure Paint;
end;
```

Whether or not the two classes share a common ancestor, they are still assignment compatible with a variable of *IPaint* as in

```
var
  Painter: IPaint;
begin
  Painter := TSquare.Create;
  Painter.Paint;
  Painter := TCircle.Create;
  Painter.Paint;
end;
```

This could have been accomplished by having *TCircle* and *TSquare* descend from a common ancestor (say, *TFigure*), which declares a virtual method *Paint*. Both *TCircle* and *TSquare* would then have overridden the *Paint* method. In the previous example, *IPaint* could be replaced by *TFigure*. However, consider the following interface:

```
IRotate = interface
  procedure Rotate(Degrees: Integer);
end;
```

IRotate makes sense for the rectangle but not the circle. The classes would look like

```
TSquare = class(TRectangularObject, IPaint, IRotate)
  procedure Paint;
  procedure Rotate(Degrees: Integer);
end;
TCircle = class(TCustomShape, IPaint)
  procedure Paint;
end;
```

Later, you could create a class *TFilledCircle* that implements the *IRotate* interface to allow rotation of a pattern that fills the circle without having to add rotation to the simple circle.

Note: For these examples, the immediate base class or an ancestor class is assumed to have implemented the methods of *IInterface*, the base interface from which all interfaces descend. For more information on *IInterface*, see Implementing IInterface (see page 2075) and Memory management of interface objects (see page 2075).

Using Interfaces in Distributed Applications (see page 2079)

3.2.4.9.19 Using Implements for Delegation

Many classes have properties that are subobjects. You can also use interfaces as property types. When a property is of an interface type (or a class type that implements the methods of an interface) you can use the keyword implements to specify that the methods of that interface are delegated to the object or interface reference which is the value of the property. The delegate only needs to provide implementation for the methods. It does not have to declare the interface support. The class containing the property must include the interface in its ancestor list.

By default, using the implements keyword delegates all interface methods. However, you can use methods resolution clauses or declare methods in your class that implement some of the interface methods to override this default behavior.

The following example uses the implements keyword in the design of a color adapter object that converts an 8-bit RGB color value to a *Color* reference:

```
unit cadapt;
interface
type
IRGB8bit = interface
['{1d76360a-f4f5-11d1-87d4-00c04fb17199}']
    function Red: Byte;
    function Green: Byte;
    function Blue: Byte;
  end;
IColorRef = interface
['{1d76360b-f4f5-11d1-87d4-00c04fb17199}']
    function Color: Integer;
  end;
{ TRGB8ColorRefAdapter   map an IRGB8bit to an IColorRef }
TRGB8ColorRefAdapter = class(TInterfacedObject, IRGB8bit, IColorRef)
  private
    FRGB8bit: IRGB8bit;
    FPalRelative: Boolean;
  public
    constructor Create(rgb: IRGB8bit);
    property RGB8Intf: IRGB8bit read FRGB8bit implements IRGB8bit;
    property PalRelative: Boolean read FPalRelative write FPalRelative;
    function Color: Integer;
  end;
implementation
constructor TRGB8ColorRefAdapter.Create(rgb: IRGB8bit);
begin
  FRGB8bit := rgb;
end;
function TRGB8ColorRefAdapter.Color: Integer;
begin
  if FPalRelative then
    Result := PaletteRGB(RGB8Intf.Red, RGB8Intf.Green, RGB8Intf.Blue)
  else
    Result := RGB(RGB8Intf.Red, RGB8Intf.Green, RGB8Intf.Blue);
end;
end.
```

Aggregation (see page 2074)

Implementing IInterface (see page 2075)

3.2.4.9.20 Using Interfaces

Delphi is a single-inheritance language. That means that any class has only a single direct ancestor. However, there are times you want a new class to inherit properties and methods from more than one base class so that you can use it sometimes like one and sometimes like the other. Interfaces let you achieve something like this effect.

An interface is like a class that contains only abstract methods (methods with no implementation) and a clear definition of their functionality. Interface method definitions include the number and types of their parameters, their return type, and their expected behavior. By convention, interfaces are named according to their behavior and prefaced with a capital *I*. For example, an *IMalloc* interface would allocate, free, and manage memory. Similarly, an *IPersist* interface could be used as a general base interface for descendants, each of which defines specific method prototypes for loading and saving the state of an object to a storage, stream, or file.

An interface has the following syntax:

```
IMyObject = interface
  procedure MyProcedure;
end;
```

A simple example of an interface declaration is:

```
type
IEdit = interface
  procedure Copy;
  procedure Cut;
  procedure Paste;
  function Undo: Boolean;
end;
```

Interfaces can never be instantiated. To use an interface, you need to obtain it from an implementing class.

To implement an interface, define a class that declares the interface in its ancestor list, indicating that it will implement all of the methods of that interface:

```
TEditor = class(TInterfacedObject, IEdit)
  procedure Copy;
  procedure Cut;
  procedure Paste;
  function Undo: Boolean;
end;
```

While interfaces define the behavior and signature of their methods, they do not define the implementations. As long as the class's implementation conforms to the interface definition, the interface is fully polymorphic, meaning that accessing and using the interface is the same for any implementation of it.

What is an Object? (see page 2071)

3.2.4.9.21 Using Interfaces in Distributed Applications

In VCL applications, interfaces are a fundamental element in the COM and SOAP distributed object models. Delphi provides base classes for these technologies that extend the basic interface functionality in *TInterfacedObject*, which simply implements the *IInterface* interface methods.

When using COM, classes and interfaces are defined in terms of *IUnknown* rather than *IInterface*. There is no semantic difference between *IUnknown* and *IInterface*, the use of *IUnknown* is simply a way to adapt Delphi interfaces to the COM definition. COM classes add functionality for using class factories and class identifiers (CLSIDs). Class factories are responsible for creating class instances via CLSIDs. The CLSIDs are used to register and manipulate COM classes. COM classes that have class factories and class identifiers are called CoClasses. CoClasses take advantage of the versioning capabilities of

QueryInterface, so that when a software module is updated *QueryInterface* can be invoked at runtime to query the current capabilities of an object.

New versions of old interfaces, as well as any new interfaces or features of an object, can become immediately available to new clients. At the same time, objects retain complete compatibility with existing client code; no recompilation is necessary because interface implementations are hidden (while the methods and parameters remain constant). In COM applications, developers can change the implementation to improve performance, or for any internal reason, without breaking any client code that relies on that interface. For more information about COM interfaces, see Overview of COM technologies (see page 1385).

When distributing an application using SOAP, interfaces are required to carry their own runtime type information (RTTI). The compiler only adds RTTI to an interface when it is compiled using the {$M+} switch. Such interfaces are called *invokable interfaces*. The descendant of any invokable interface is also invokable. However, if an invokable interface descends from another interface that is not invokable, client applications can only call the methods defined in the invokable interface and its descendants. Methods inherited from the non-invokable ancestors are not compiled with type information and so can't be called by clients.

The easiest way to define invokable interfaces is to define your interface so that it descends from *IInvokable*. *IInvokable* is the same as *IInterface*, except that it is compiled using the {$M+} switch. For more information about Web Service applications that are distributed using SOAP, and about invokable interfaces, see Using Web Services (see page 2291).

Using the As Operator with Interfaces (see page 2082)

Reusing Code and Delegation (see page 2076)

Memory Management of Interface Objects (see page 2075)

Using Interfaces Across the Hierarchy (see page 2077)

3.2.4.9.22 Using Interfaces with Procedures

Interfaces allow you to write generic procedures that can handle objects without requiring that the objects descend from a particular base class. Using the *IPaint* and *IRotate* interfaces defined previously, you can write the following procedures:

```
procedure PaintObjects(Painters: array of IPaint);
var
  I: Integer;
begin
  for I := Low(Painters) to High(Painters) do
    Painters[I].Paint;
end;
procedure RotateObjects(Degrees: Integer; Rotaters: array of IRotate);
var
  I: Integer;
begin
  for I := Low(Rotaters) to High(Rotaters) do
    Rotaters[I].Rotate(Degrees);
end;
```

RotateObjects does not require that the objects know how to paint themselves and *PaintObjects* does not require the objects know how to rotate. This allows the generic procedures to be used more often than if they were written to only work against a *TFigure* class.

Memory Management of Interface Objects (see page 2075)

Using Interfaces in Distributed Applications (see page 2079)

3.2.4.9.23 Using Reference Counting

The Delphi compiler provides most of the *IInterface* memory management for you by its implementation of interface querying and reference counting. Therefore, if you have an object that lives and dies by its interfaces, you can easily use reference counting by deriving from *TInterfacedObject*. If you decide to use reference counting, then you must be careful to only hold the object as an interface reference, and to be consistent in your reference counting. For example:

```
procedure beep(x: ITest);
function test_func()
var
  y: ITest;
begin
  y := TTest.Create; // because y is of type ITest, the reference count is one
  beep(y); // the act of calling the beep function increments the reference count
  // and then decrements it when it returns
  y.something; // object is still here with a reference count of one
end;
```

This is the cleanest and safest approach to memory management; and if you use *TInterfacedObject* it is handled automatically. If you do not follow this rule, your object can unexpectedly disappear, as demonstrated in the following code:

```
function test_func()
var
  x: TTest;
begin
  x := TTest.Create; // no count on the object yet
  beep(x as ITest); // count is incremented by the act of calling beep
  // and decremented when it returns
  x.something; // surprise, the object is gone
end;
```

Note: In the examples above, the *beep* procedure, as it is declared, increments the reference count (call *_AddRef*) on the parameter, whereas either of the following declarations do not:

```
procedure beep(const x: ITest);
```

or

```
procedure beep(var x: ITest);
```

These declarations generate smaller, faster code.

One case where you cannot use reference counting, because it cannot be consistently applied, is if your object is a component or a control owned by another component. In that case, you can still use interfaces, but you should not use reference counting (see page 2076) because the lifetime of the object is not dictated by its interfaces.

See Also

Not Using Reference Counting (see page 2076)

3.2.4.9.24 Using the as Operator with Interfaces

Classes that implement interfaces can use the as operator for dynamic binding on the interface. In the following example,

```
procedure PaintObjects(P: TInterfacedObject)
var
  X: IPaint;
begin
  X := P as IPaint;
{ statements }
end;
```

the variable *P* of type *TInterfacedObject*, can be assigned to the variable *X,* which is an *IPaint* interface reference. Dynamic binding makes this assignment possible. For this assignment, the compiler generates code to call the *QueryInterface* method of *P*'s *IInterface* interface. This is because the compiler cannot tell from *P*'s declared type whether *P*'s instance actually supports *IPaint*. At runtime, *P* either resolves to an *IPaint* reference or an exception is raised. In either case, assigning *P* to *X* will not generate a compile-time error as it would if *P* was of a class type that did not implement *IInterface*.

When you use the as operator for dynamic binding on an interface, you should be aware of the following requirements:

- Explicitly declaring *IInterface*: Although all interfaces derive from *IInterface*, it is not sufficient, if you want to use the as operator, for a class to simply implement the methods of *IInterface*. This is true even if it also implements the interfaces it explicitly declares. The class must explicitly declare *IInterface* in its interface list.
- Using an IID: Interfaces can use an identifier that is based on a GUID (globally unique identifier). GUIDs that are used to identify interfaces are referred to as interface identifiers (IIDs). If you are using the as operator with an interface, it must have an associated IID. To create a new GUID in your source code you can use the `Ctrl+Shift+G` editor shortcut key.

Memory Management of Interface Objects (see page 2075)

3.2.4.10 Using the VCL/RTL

Topics

Name	Description
Using the VCL/RTL: Overview (see page 2090)	There are a number of units in the component library that provide the underlying support for most of the component libraries. These units include the global routines that make up the runtime library, a number of utility classes such as those that represent streams and lists, and the classes *TObject*, *TPersistent*, and *TComponent*. Collectively, these units are called the VCL/RTL. The VCL/RTL does not include any of the components that appear on the **Tool Palette**. Rather, the classes and routines in the VCL/RTL are used by the components that do appear on the **Tool Palette** and... more (see page 2090)
Adding New Measurement Types (see page 2091)	If you want to perform conversions between measurement units not already defined in the StdConvs unit, you need to create a new conversion family to represent the measurement units (*TConvType* values). When two *TConvType* values are registered with the same conversion family, the *Convert* function can convert between measurements made using the units represented by those *TConvType* values. You first need to obtain *TConvFamily* values by registering a conversion family using the RegisterConversionFamily function. After you get a *TConvFamily* value (by registering a new conversion family or using one of the global variables in the StdConvs unit),... more (see page 2091)

Approaches to File I/O (see page 2091)	There are several approaches you can take when reading from and writing to files: • The recommended approach for working with files is to use file streams. File streams are instances of the *TFileStream* class used to access information in disk files. File streams are a portable and high-level approach to file I/O. Because file streams make the file handle available, this approach can be combined with the next one. The Using file streams (see page 2133) discusses *TFileStream* in detail. • You can work with files using a handle-based approach. File handles are provided by the operating system when you create or open a... more (see page 2091)
Common List Operations (see page 2091)	Although the various list classes contain different types of items and have different ancestries, most of them share a common set of methods for adding, deleting, rearranging, and accessing the items in the list.
Converting Measurements (see page 2092)	The ConvUtils unit declares a general-purpose Conversion Function (see page 2113) that you can use to convert a measurement from one set of units to another. You can perform conversions between compatible units of measurement such as feet and inches or days and weeks. Units that measure the same types of things are said to be in the same *conversion family*. The units you're converting must be in the same conversion family. For information on doing conversions, see Performing Conversions (see page 2105). The StdConvs unit defines several conversion families and measurement units within each family. In addition, you can create customized... more (see page 2092)
Copying and Clearing Custom Variants (see page 2093)	In addition to typecasting and the implementation of operators, you must indicate how to copy and clear variants of your custom Variant type. To indicate how to copy the variant's value, implement the Copy method. Typically, this is an easy operation, although you must remember to allocate memory for any classes or structures you use to hold the variant's value:
Copying Data from One Stream to Another (see page 2094)	When copying data from one stream to another, you do not need to explicitly read and then write the data. Instead, you can use the *CopyFrom* method, as illustrated in the following example. In the following example, one file is copied to another one using streams. The application includes two edit controls (*EdFrom* and *EdTo*) and a *Copy File* button.
Creating a Class to Enable the Custom Variant Type (see page 2094)	Custom variants work by using a special helper class that indicates how variants of the custom type can perform standard operations. You create this helper class by writing a descendant of TCustomVariantType. This involves overriding the appropriate virtual methods of *TCustomVariantType*. The following topics provide details on how to implement and use a TCustomVariantType descendant: • Enabling casting (see page 2097) • Implementing binary operations (see page 2100) • Implementing comparison operations (see page 2102) • Implementing unary operations (see page 2103) • Copying and clearing custom variants (see page 2093) • Loading and saving custom variant values (see page 2104) • Using the TCustomVariantType descendant (see page 2116)
Creating a Simple Conversion Family and Adding Units (see page 2095)	One example of when you could create a new conversion family and add new measurement types might be when performing conversions between long periods of time (such as months to centuries) where a loss of precision can occur. To explain this further, the *cbTime* family uses a day as its base unit. The base unit is the one that is used when performing all conversions within that family. Therefore, all conversions must be done in terms of days. An inaccuracy can occur when performing conversions using units of months or larger (months, years, decades, centuries, millennia) because there is not... more (see page 2095)

Defining Custom Variants (see page 2096)	One powerful built-in type of the Delphi language is the Variant type. Variants represent values whose type is not determined at compile time. Instead, the type of their value can change at runtime. Variants can mix with other variants and with integer, real, string, and boolean values in expressions and assignments; the compiler automatically performs type conversions. By default, variants can't hold values that are records, sets, static arrays, files, classes, class references, or pointers. You can, however, extend the Variant type to work with any particular example of these types. All you need to do is create... more (see page 2096)
Enabling Casting (see page 2097)	One of the most important features of the custom variant type for you to implement is typecasting. The flexibility of variants arises, in part, from their implicit typecasts. There are two methods for you to implement that enable the custom Variant type to perform typecasts: Cast, which converts another variant type to your custom variant, and CastTo, which converts your custom Variant type to another type of Variant. When implementing either of these methods, it is relatively easy to perform the logical conversions from the built-in variant types. You must consider, however, the possibility that the variant to or from... more (see page 2097)
Use __fastcall When Overriding VCL Methods (see page 2098)	Member functions for VCL classes generally use __fastcall in their declaration unless declared otherwise. This means that you must use __fastcall in the declaration of any VCL class member function that you override.
Working with ini Files and the System Registry (see page 2099)	Many applications use ini files to store configuration information. The VCL/RTL includes two classes for working with ini files: *TIniFile* and *TMemIniFile*. Using ini files has the advantage that they can be used in cross-platform applications and they are easy to read and edit. For information on these classes, see Using TIniFile and TMemIniFile (see page 2131) for more information. Many Windows applications replace the use of ini files with the system Registry. The Windows system Registry is a hierarchical database that acts as a centralized storage space for configuration information. The VCL includes classes for working with the... more (see page 2099)
Using Streams (see page 2099)	Streams are classes that let you read and write data. They provide a common interface for reading and writing to different media such as memory, strings, sockets, and BLOB fields in databases. There are several stream classes, which all descend from *TStream*. Each stream class is specific to one media type. For example, *TMemoryStream* reads from or writes to a memory image; *TFileStream* reads from or writes to a file. The following topics describe the methods common to all stream classes: • Using streams to read or write data (see page 2115) • Copying data from one stream to another (see page 2094) • Specifying the stream position (see page 2106)... more (see page 2099)
Using TRegistry (see page 2099)	If you are writing a Windows-only application and are comfortable with the structure of the system Registry, you can use *TRegistry*. Unlike *TRegistryIniFile*, which uses the same properties and methods of other ini file components, the properties and methods of *TRegistry* correspond more directly to the structure of the system Registry. You can specify both the root key and subkey using *TRegistry*, while *TRegistryIniFile* uses `HKEY_CURRENT_USER` as the root key. In addition to methods for opening, closing, saving, moving, copying, and deleting keys, *TRegistry* lets you specify the access level you want to... more (see page 2099)
Implementing Binary Operations (see page 2100)	To allow the custom variant type to work with standard binary operators (+, -, *, /, div, mod, shl, shr, and, or, xor listed in the System unit), you must override the BinaryOp method. *BinaryOp* has three parameters: the value of the left-hand operand, the value of the right-hand operand, and the operator. Implement this method to perform the operation and return the result using the same variable that contained the left-hand operand. For example, the following *BinaryOp* method comes from the *TComplexVariantType* defined in the VarCmplx unit:
Implementing Comparison Operations (see page 2102)	There are two ways to enable a custom variant type to support comparison operators (=, <>, <, <=, >, >=). You can override the *Compare* method, or you can override the *CompareOp* method. The Compare method is easiest if your custom variant type supports the full range of comparison operators. *Compare* takes three parameters: the left-hand operand, the right-hand operand, and a var Parameter that returns the relationship between the two. For example, the *TConvertVariantType* object in the VarConv unit implements the following *Compare* method:

Implementing Unary Operations (see page 2103)	To allow the custom variant type to work with standard unary operators (-, not), you must override the UnaryOp method. *UnaryOp* has two parameters: the value of the operand and the operator. Implement this method to perform the operation and return the result using the same variable that contained the operand. For example, the following *UnaryOp* method comes from the *TComplexVariantType* defined in the VarCmplx unit:
Loading and Saving Custom Variant Values (see page 2104)	By default, when the custom variant is assigned as the value of a published property, it is typecast to a string when that property is saved to a form file, and converted back from a string when the property is read from a form file. You can, however, provide your own mechanism for loading and saving custom variant values in a more natural representation. To do so, the *TCustomVariantType* descendant must implement the IVarStreamable interface from Classes.pas. *IVarStreamable* defines two methods, *StreamIn* and *StreamOut*, for reading a variant's value from a stream and for writing the variant's value to... more (see page 2104)
Performing Conversions (see page 2105)	You can use the *Convert* function to perform both simple and complex conversions. It includes a simple syntax and a second syntax for performing conversions between complex measurement types.
Persistent Lists (see page 2105)	Persistent lists can be saved to a form file. Because of this, they are often used as the type of a published property on a component. You can add items to the list at design time, and those items are saved with the object so that they are there when the component that uses them is loaded into memory at runtime. There are two main types of persistent lists: string lists and collections. Examples of string lists include *TStringList* and *THashedStringList*. String lists, as the name implies, contain strings. They provide special support for strings of the form Name=Value,... more (see page 2105)
Specifying the Stream Position and Size (see page 2106)	In addition to methods for reading and writing, streams permit applications to seek to an arbitrary position in the stream or change the size of the stream. Once you seek to a specified position, the next read or write operation starts reading from or writing to the stream at that position.
Storing a Custom Variant Type's Data (see page 2107)	Variants store their data in the *TVarData* record type. This type is a record that contains 16 bytes. The first word indicates the type of the variant, and the remaining 14 bytes are available to store the data. While your new Variant type can work directly with a *TVarData* record, it is usually easier to define a record type whose members have names that are meaningful for your new type, and cast that new type onto the *TVarData* record type. For example, the VarConv unit defines a custom variant type that represents a measurement. The data for this... more (see page 2107)
String Dependencies (see page 2108)	Sometimes you need to convert a long string to a null-terminated string, for example, if you are using a function that takes a *PChar*. If you must cast a string to a *PChar*, be aware that you are responsible for the lifetime of the resulting *PChar*. Because long strings are reference counted, typecasting a string to a *PChar* increases the dependency on the string by one, without actually incrementing the reference count. When the reference count hits zero, the string will be destroyed, even though there is an extra dependency on it. The cast *PChar* will also... more (see page 2108)
Supporting Properties and Methods in Custom Variants (see page 2108)	Some variants have properties and methods. For example, when the value of a variant is an interface, you can use the variant to read or write the values of properties on that interface and call its methods. Even if your custom variant type does not represent an interface, you may want to give it properties and methods that an application can use in the same way.
Using a Class to Manage Conversions (see page 2110)	You can always use conversion functions to register a conversion unit. There are times, however, when this requires you to create an unnecessarily large number of functions that all do essentially the same thing. If you can write a set of conversion functions that differ only in the value of a parameter or variable, you can create a class to handle those conversions. For example, there is a set standard techniques for converting between the various European currencies since the introduction of the Euro. Even though the conversion factors remain constant (unlike the conversion factor between, say, dollars and Euros),... more (see page 2110)
Using a Conversion Function (see page 2113)	For cases when the conversion is more complex, you can use a different syntax to specify a function to perform the conversion instead of using a conversion factor. For example, you can't convert temperature values using a conversion factor, because different temperature scales have a different origins. This example, which comes from the StdConvs unit, shows how to register a conversion type by providing functions to convert to and from the base units.

Using Streams to Read or Write Data (see page 2115)	Stream classes all share several methods for reading and writing data. These methods are distinguished by whether they: • Return the number of bytes read or written. • Require the number of bytes to be known. • Raise an exception on error.
Using the TCustomVariantType Descendant (see page 2116)	In the initialization section of the unit that defines your *TCustomVariantType* descendant, create an instance of your class. When you instantiate your object, it automatically registers itself with the variant-handling system so that the new Variant type is enabled. For example, here is the initialization section of the VarCmplx unit:
Writing Utilities to Work with a Custom Variant Type (see page 2117)	Once you have created a *TCustomVariantType* descendant to implement your custom variant type, it is possible to use the new Variant type in applications. However, without a few utilities, this is not as easy as it should be. It is a good idea to create a method that creates an instance of your custom variant type from an appropriate value or set of values. This function or set of functions fills out the structure you defined (see page 2107) to store your custom variant's data. For example, the following function could be used to create a complex-valued variant:
Commonly Used Long String Routines (see page 2118)	The string handling routines in `SysUtils` handle both **UnicodeString** and **AnsiString** types. Within their functional areas, some routines are used for the same purpose, the differences being whether they use a particular criterion in their calculations. The `AnsiStrings` unit's functions offer the same capabilities as the `SysUtils` unit's routines. `AnsiStrings` functions provide better performance for **AnsiString** than `SysUtils` functions, because `SysUtils` functions convert an **AnsiString** to a **UnicodeString**. `AnsiStrings` functions work only with **AnsiString**, so there is no conversion. The following tables list these routines by these functional areas: • Comparison • Case... more (see page 2118)
Commonly Used Routines for Null-terminated Strings (see page 2121)	The null-terminated string handling routines cover several functional areas. Within these areas, some are used for the same purpose, the differences being whether or not they use a particular criteria in their calculations. The following tables list these routines by these functional areas: • Comparison • Case conversion • Modification • Sub-string • Copying Where appropriate, the tables also provide columns indicating whether the routine is case-sensitive, uses the current locale, and/or supports multi-byte character sets. ***Null-terminated string comparison routines***
Compiler Directives for Strings (see page 2122)	The following compiler directives affect character and string types. ***Compiler directives for strings***
Copying a File (see page 2123)	The runtime library does not provide any routines for copying a file. However, if you are writing Windows-only applications, you can directly call the Windows API *CopyFile* function to copy a file. Like most of the runtime library file routines, *CopyFile* takes a filename as a parameter, not a file handle. When copying a file, be aware that the file attributes for the existing file are copied to the new file, but the security attributes are not. *CopyFile* is also useful when moving files across drives because neither the *RenameFile* function nor the Windows API *MoveFile* function can rename or... more (see page 2123)
Declaring and Initializing Strings (see page 2123)	When you declare a string:
Deleting a File (see page 2124)	Deleting a file erases the file from the disk and removes the entry from the disk's directory. There is no corresponding operation to restore a deleted file, so applications should generally allow users to confirm before deleting files. To delete a file, pass the name of the file to the *DeleteFile* function:

File Date-time Routines (see page 2125)	The *FileAge*, *FileGetDate*, and *FileSetDate* routines operate on operating system date-time values. *FileAge* returns the date-and-time stamp of a file, or -1 if the file does not exist. *FileSetDate* sets the date-and-time stamp for a specified file, and returns zero on success or an error code on failure. *FileGetDate* returns a date-and-time stamp for the specified file or –1 if the handle is invalid. As with most of the file manipulating routines, *FileAge* uses a string filename. *FileGetDate* and *FileSetDate*, however, use a *Handle* type as a parameter. To get the file handle either: • Use the *FileOpen... more (see page 2125)*
Finding a File (see page 2125)	There are three routines used for finding a file: *FindFirst*, *FindNext*, and *FindClose*. *FindFirst* searches for the first instance of a filename with a given set of attributes in a specified directory. *FindNext* returns the next entry matching the name and attributes specified in a previous call to *FindFirst*. *FindClose* releases memory allocated by *FindFirst*. You should always use *FindClose* to terminate a *FindFirst*/*FindNext* sequence. If you want to know if a file exists, a *FileExists* function returns *True* if the file exists, *False* otherwise. The three file find routines take a *TSearchRec... more (see page 2125)*
Manipulating Files (see page 2127)	Several common file operations are built into the runtime library. The routines for working with files operate at a high level. For most routines, you specify the name of the file and the routine makes the necessary calls to the operating system for you. In some cases, you use file handles instead. **Warning:** Although the Delphi language is not case sensitive, the Linux operating system is. Be attentive to case when working with files in cross-platform applications. The following topics describe how to use runtime library routines to perform file manipulation tasks: • Deleting a file (see page 2124) • Finding a file (see page 2125) • Renaming a (see page 2130)... more (see page 2127)
Mixing and Converting String Types (see page 2127)	Short, long, and wide strings can be mixed in assignments and expressions, and the compiler automatically generates code to perform the necessary string type conversions. However, when assigning a string value to a short string variable, be aware that the string value is truncated if it is longer than the declared maximum length of the short string variable. Long strings are already dynamically allocated. If you use one of the built-in pointer types, such as *PAnsiString*, *PString*, or *PWideString*, remember that you are introducing another level of indirection. Be sure this is what you intend.
Passing a Local Variable as a PChar (see page 2128)	Consider the case where you have a local string variable that you need to initialize by calling a function that takes a *PChar*. One approach is to create a local **array of char** and pass it to the function, then assign that variable to the string:
Creating Drawing Spaces (see page 2128)	The *TCanvas* class is defined in the Graphics unit, and encapsulates a Windows device context. This class handles all drawing for forms, visual containers (such as panels) and the printer object (see Printing (see page 2129)). Using the canvas object, you need not worry about allocating pens, brushes, palettes, and so on—all the allocation and deallocation are handled for you. *TCanvas* includes a large number of primitive graphics routines to draw lines, shapes, polygons, fonts, etc. onto any control that contains a canvas. For example, here is a button event handler that draws a line from the upper left corner to... more (see page 2128)
Printing (see page 2129)	The VCL *TPrinter* object encapsulates details of Windows printers. To get a list of installed and available printers, use the *Printers* property. Both printer objects use a *TCanvas* (which is identical to the form's *TCanvas*) which means that anything that can be drawn on a form can be printed as well. To print an image, call the *BeginDoc* method followed by whatever canvas graphics you want to print (including text through the *TextOut* method) and send the job to the printer by calling the *EndDoc* method. This example uses a button and a memo on a form. When... more (see page 2129)
Using TRegistryIniFile (see page 2130)	Many 32-bit Windows applications store their information in the system Registry instead of ini files because the Registry is hierarchical and doesn't suffer from the size limitations of ini files. If you are accustomed to using ini files and want to move your configuration information to the Registry instead, you can use the *TRegistryIniFile* class. You may also want to use *TRegistryIniFile* in cross-platform applications if you want to use the system Registry on Windows and an ini file on Linux. You can write most of your application so that it uses the *TCustomIniFile* type. You... more (see page 2130)

Renaming a File (see page 2130)	To change a file name, use the *RenameFile* function:
Returning a PChar Local Variable (see page 2131)	A common error when working with *PChars* is to store a local variable in a data structure, or return it as a value. When your routine ends, the *PChar* disappears because it is a pointer to memory, and not a reference counted copy of the string. For example:
String to PChar Conversions (see page 2131)	Long string (**AnsiString** and **UnicodeString**) to *PChar* conversions are not automatic. Some of the differences between strings and *PChars* can make conversions problematic: • Long strings are reference-counted, while *PChars* are not. • Assigning to a string copies the data, while a *PChar* is a pointer to memory. • Long strings are null-terminated and also contain the length of the string and other information, while *PChars* are simply null-terminated. Situations in which these differences can cause subtle errors are discussed in the following topics: • String dependencies (see page 2108) • Returning a PChar local variable (see page 2131) • Passing a local variable as a PChar (see page 2128)
Using TIniFile and TMemIniFile (see page 2131)	The ini file format is still popular, many configuration files (such as the DSK Desktop settings file) are in this format. This format is especially useful in cross-platform applications, where you can't always count on a system Registry for storing configuration information. The VCL/RTL provides two classes, *TIniFile* and *TMemIniFile*, to make reading and writing ini files very easy. *TIniFile* works directly with the ini file on disk while *TMemIniFile* buffers all changes in memory and does not write them to disk until you call the *UpdateFile* method. When you instantiate the *TIniFile* or *TMemIniFile* object, you pass... more (see page 2131)
Using File Streams (see page 2133)	The *TFileStream* class enables applications to read from and write to a file on disk. Because *TFileStream* is a stream object, it shares the common stream methods. You can use these methods to read from or write to the file, copy data to or from other stream classes, and read or write components values. See Using streams (see page 2099) for details on the capabilities that files streams inherit by being stream classes. In addition, file streams give you access to the file handle, so that you can use them with global file handling routines that require the file handle.
Accessing a Particular String (see page 2134)	The *Strings* array property contains the strings in the list, referenced by a zero-based index. Because *Strings* is the default property for string lists, you can omit the *Strings* identifier when accessing the list; thus
Adding a String to a List (see page 2134)	To add a string to the end of a string list, call the *Add* method, passing the new string as the parameter. To insert a string into the list, call the *Insert* method, passing two parameters: the string and the index of the position where you want it placed. For example, to make the string "Three" the third string in a list, you would use:
Associating Objects with a String List (see page 2135)	In addition to the strings stored in its *Strings* property, a string list can maintain references to *objects*, which it stores in its *Objects* property. Like *Strings*, *Objects* is an array with a zero-based index. The most common use for *Objects* is to associate bitmaps with strings for owner-draw controls. Use the *AddObject* or *InsertObject* method to add a string and an associated object to the list in a single step. *IndexOfObject* returns the index of the first string in the list associated with a specified object. Methods like *Delete*, *Clear*, and *Move* operate on both... more (see page 2135)
Copying a Complete String List (see page 2135)	You can use the *Assign* method to copy strings from a source list to a destination list, overwriting the contents of the destination list. To append strings without overwriting the destination list, use *AddStrings*. For example,
Counting the Strings in a List (see page 2135)	The read-only *Count* property returns the number of strings in the list. Since string lists use zero-based indexes, *Count* is one more than the index of the last string.

Creating a New String List (see page 2135)	A string list is typically part of a component. There are times, however, when it is convenient to create independent string lists, for example to store strings for a lookup table. The way you create and manage a string list depends on whether the list is short-term (constructed, used, and destroyed in a single routine) or long-term (available until the application shuts down). Whichever type of string list you create, remember that you are responsible for freeing the list when you finish with it.
Deleting a String from a List (see page 2137)	To delete a string from a string list, call the list's *Delete* method, passing the index of the string you want to delete. If you don't know the index of the string you want to delete, use the *IndexOf* method to locate it. To delete all the strings in a string list, use the *Clear* method. The following example uses *IndexOf* and *Delete* to find and delete a string:
Locating Items in a String List (see page 2138)	To locate a string in a string list, use the *IndexOf* method. *IndexOf* returns the index of the first string in the list that matches the parameter passed to it, and returns –1 if the parameter string is not found. *IndexOf* finds exact matches only; if you want to match partial strings, you must iterate through the string list yourself. For example, you could use *IndexOf* to determine whether a given file name is found among the Items of a list box:
Iterating Through Strings in a List (see page 2138)	To iterate through the strings in a list, use a **for** loop that runs from zero to *Count* –1. The following example converts each string in a list box to uppercase characters.
Loading and Saving String Lists (see page 2138)	String-list objects provide *SaveToFile* and *LoadFromFile* methods that let you store a string list in a text file and load a text file into a string list. Each line in the text file corresponds to a string in the list. Using these methods, you could, for example, create a simple text editor by loading a file into a memo component, or save lists of items for combo boxes. The following example loads a copy of the MyFile.ini file into a memo field and makes a backup copy called MyFile.bak.
Manipulating Strings in a List (see page 2139)	Operations commonly performed on string lists include: • Counting the strings in a list (see page 2135) • Accessing a particular string (see page 2134) • Finding the position of a string in the list (see page 2138) • Iterating through strings in a list (see page 2138) • Adding a string to a list (see page 2134) • Moving a string within a list • Deleting a string from a list (see page 2137) • Copying a complete string list (see page 2135)
Working with Lists (see page 2139)	The VCL/RTL includes many classes that represents lists or collections of items. They vary depending on the types of items they contain, what operations they support, and whether they are persistent. The following table lists various list classes, and indicates the types of items they contain:
Working with String Lists (see page 2140)	One of the most commonly used types of list is a list of character strings. Examples include items in a combo box, lines in a memo, names of fonts, and names of rows and columns in a string grid. The VCL/RTL provides a common interface to any list of strings through an object called *TStrings* and its descendants such as *TStringList* and *THashedStringList*. *TStringList* implements the abstract properties and methods introduced by *TStrings*, and introduces properties, events, and methods to • Sort the strings in the list. • Prohibit duplicate strings in sorted lists. • Respond to changes in the contents... more (see page 2140)

Wide Character Routines (see page 2141)	Wide strings contain two bytes per element and are used in a variety of situations. You may also choose to use wide strings because they simplify some of the string-handling issues in applications that have multiple target locales. Using a wide character encoding scheme has the advantage that you can make many of the usual assumptions about strings that do not work for MBCS systems, which are single byte strings. For wide strings, there is a direct relationship between the number of bytes in the string and the number of elements in the string. In a MBCS string, you have... more (see page 2141)
Working with Files (see page 2142)	The VCL/RTL supports several ways of working with files. In addition to using file streams, there are several runtime library routines for performing file I/O. Both file streams and the global routines for reading from and writing to files are described in Approaches to file I/O (see page 2091). In addition to input/output operations, you may want to manipulate files on disk. Support for operations on the files themselves rather than their contents is described in Manipulating files (see page 2127). **Note:** When writing cross-platform applications, remember that although the Delphi language is not case sensitive, the Linux operating system is. When using objects... more (see page 2142)
Working with Strings (see page 2142)	The runtime library provides many specialized string-handling routines specific to a string type. These are routines for strings (`AnsiString` and `UnicodeString`), wide strings (`WideString`), and null-terminated strings (`PChars`). Routines that deal with null-terminated strings use the null-termination to determine the length of the string. There are no categories of routines listed for *ShortString* types. However, some built-in compiler routines deal with the *ShortString* type. These include, for example, the `Low` and `High` standard functions. For more details about the various string types, see the *Delphi Language Guide*. The following topics provide an overview... more (see page 2142)

3.2.4.10.1 Using the VCL/RTL: Overview

There are a number of units in the component library that provide the underlying support for most of the component libraries. These units include the global routines that make up the runtime library, a number of utility classes such as those that represent streams and lists, and the classes *TObject*, *TPersistent*, and *TComponent*. Collectively, these units are called the VCL/RTL. The VCL/RTL does not include any of the components that appear on the **Tool Palette**. Rather, the classes and routines in the VCL/RTL are used by the components that do appear on the **Tool Palette** and are available for you to use in application code or when you are writing your own classes.

The following topics discuss many of the classes and routines that make up the VCL/RTL and illustrate how to use them.

- Using streams (see page 2099)
- Working with files (see page 2142)
- Working with .ini files (see page 2099)
- Working with lists (see page 2139)
- Working with string lists (see page 2140)
- Working with strings (see page 2142)
- Creating drawing spaces (see page 2128)
- Printing (see page 2129)
- Converting measurements (see page 2092)
- Defining custom variants (see page 2096)

Note: This list of tasks is not exhaustive. The runtime library in the VCL/RTL contains many routines to perform tasks that are not mentioned here. These include a host of mathematical functions (defined in the Math unit), routines for working with date/time values (defined in the SysUtils and DateUtils units), and routines for working with Variant values (defined in the Variants unit).

Understanding the Component Library (see page 2055)

Overview of Component Creation (see page 1313)

3.2.4.10.2 Adding New Measurement Types

If you want to perform conversions between measurement units not already defined in the StdConvs unit, you need to create a new conversion family to represent the measurement units (*TConvType* values). When two *TConvType* values are registered with the same conversion family, the *Convert* function can convert between measurements made using the units represented by those *TConvType* values.

You first need to obtain *TConvFamily* values by registering a conversion family using the RegisterConversionFamily function. After you get a *TConvFamily* value (by registering a new conversion family or using one of the global variables in the StdConvs unit), you can use the RegisterConversionType function to add the new units to the conversion family. The following examples show how to do this:

Creating a simple conversion family and adding units (see page 2095)

Using a conversion function (see page 2113)

Using a class to manage conversions (see page 2110)

For more examples, refer to the source code for the standard conversions unit (stdconvs.pas). (Note that the source is not included in all editions of Delphi.)

See Also

Performing Conversions (see page 2105)

3.2.4.10.3 Approaches to File I/O

There are several approaches you can take when reading from and writing to files:

- The recommended approach for working with files is to use file streams. File streams are instances of the *TFileStream* class used to access information in disk files. File streams are a portable and high-level approach to file I/O. Because file streams make the file handle available, this approach can be combined with the next one. The Using file streams (see page 2133) discusses *TFileStream* in detail.
- You can work with files using a handle-based approach. File handles are provided by the operating system when you create or open a file to work with its contents. The SysUtils unit defines a number of file-handling routines that work with files using file handles. On Windows, these are typically wrappers around Windows API functions. Because the VCL/RTL functions can use the Delphi language syntax, and occasionally provide default parameter values, they are a convenient interface to the Windows API. Furthermore, there are corresponding versions on Linux, so you can use these routines in cross-platform applications. To use a handle-based approach, you first open a file using the *FileOpen* function or create a new file using the *FileCreate* function. Once you have the handle, use handle-based routines to work with its contents (write a line, read text, and so on).
- The System unit defines a number of file I/O routines that work with file variables, usually of the format "F: Text:" or "F: File:" File variables can have one of three types: typed, text, and untyped. A number of file-handling routines, such as *AssignPrn* and *writeln*, use them. The use of file variables is deprecated, and these file types are supported only for backward compatibility. They are incompatible with Windows file handles.

Manipulating Files (see page 2127)

3.2.4.10.4 Common List Operations

Although the various list classes contain different types of items and have different ancestries, most of them share a common set of methods for adding, deleting, rearranging, and accessing the items in the list.

Adding list items

Most list classes have an *Add* method, which lets you add an item to the end of the list (if it is not sorted) or to its appropriate position (if the list is sorted). Typically, the *Add* method takes as a parameter the item you are adding to the list and returns the position in the list where the item was added. In the case of bucket lists (*TBucketList* and *TObjectBucketList*), *Add* takes not only the item to add, but also a datum you can associate with that item. In the case of collections, *Add* takes no parameters, but creates a new item that it adds. The *Add* method on collections returns the item it added, so that you can assign values to the new item's properties.

Some list classes have an *Insert* method in addition to the *Add* method. Insert works the same way as the *Add* method, but has an additional parameter that lets you specify the position in the list where you want the new item to appear. If a class has an Add method, it also has an Insert method unless the position of items is predetermined For example, you can't use *Insert* with sorted lists because items must go in sort order, and you can't use *Insert* with bucket lists because the hash algorithm determines the item position.

The only classes that do not have an *Add* method are the ordered lists. Ordered lists are queues and stacks. To add items to an ordered list, use the *Push* method instead. *Push*, like *Add*, takes an item as a parameter and inserts it in the correct position.

Deleting list items

To delete a single item from one of the list classes, use either the *Delete* method or the *Remove* method. *Delete* takes a single parameter, the index of the item to remove. *Remove* also takes a single parameter, but that parameter is a reference to the item to remove, rather than its index. Some list classes support only a *Delete* method, some support only a *Remove* method, and some have both.

As with adding items, ordered lists behave differently than all other lists. Instead of using a *Delete* or *Remove* method, you remove an item from an ordered list by calling its *Pop* method. *Pop* takes no arguments, because there is only one item that can be removed.

If you want to delete all of the items in the list, you can call the *Clear* method. Clear is available for all lists except ordered lists.

Accessing list items

All list classes (except *TThreadList* and the ordered lists)*have a property that lets you access the items in the list. Typically, this property is called Items. For string lists, the property is called Strings, and for bucket lists it is called Data. The Items, Strings, or Data property is an indexed property, so that you can specify which item you want to access.*

On TThreadList, you must lock the list before you can access items. When you lock the list, the LockList method returns a TList object that you can use to access the items.

Ordered lists only let you access the "top" item of the list. You can obtain a reference to this item by calling the Peek method.

Rearranging list items

Some list classes have methods that let you rearrange the items in the list. Some have an *Exchange* method, that swaps the position of two items. Some have a *Move* method that lets you move an item to a specified location. Some have a *Sort* method that lets you sort the items in the list.

To see what methods are available, check the online Help for the list class you are using.

3.2.4.10.5 Converting Measurements

The ConvUtils unit declares a general-purpose Conversion Function (see page 2113) that you can use to convert a measurement from one set of units to another. You can perform conversions between compatible units of measurement such as feet and inches or days and weeks. Units that measure the same types of things are said to be in the same *conversion family*.

The units you're converting must be in the same conversion family. For information on doing conversions, see Performing Conversions (see page 2105).

The StdConvs unit defines several conversion families and measurement units within each family. In addition, you can create customized conversion families and associated units using the RegisterConversionTypeand RegisterConversionFamily functions. For information on extending conversion and conversion units, see Adding new measurement types (see page 2091).

3.2.4.10.6 Copying and Clearing Custom Variants

In addition to typecasting and the implementation of operators, you must indicate how to copy and clear variants of your custom Variant type.

To indicate how to copy the variant's value, implement the Copy method. Typically, this is an easy operation, although you must remember to allocate memory for any classes or structures you use to hold the variant's value:

```
procedure TComplexVariantType.Copy(var Dest: TVarData; const Source: TVarData;
const Indirect: Boolean);
begin
if Indirect and VarDataIsByRef(Source) then
VarDataCopyNoInd(Dest, Source)
else
with TComplexVarData(Dest) do
begin
VType := VarType;
VComplex := TComplexData.Create(TComplexVarData(Source).VComplex);
end;
end;
```

Note: The *Indirect* parameter in the *Copy* method signals that the copy must take into account the case when the variant holds only an indirect reference to its data.

Tip: If your custom variant type does not allocate any memory to hold its data (if the data fits entirely in the *TVarData* record), your implementation of the Copy method can simply call the SimplisticCopy method.

To indicate how to clear the variant's value, implement the Clear method. As with the Copy method, the only tricky thing about doing this is ensuring that you free any resources allocated to store the variant's data:

```
procedure TComplexVariantType.Clear(var V: TVarData);
begin
V.VType := varEmpty;
FreeAndNil(TComplexVarData(V).VComplex);
end;
```

You will also need to implement the IsClear method. This way, you can detect any invalid values or special values that represent "blank" data:

```
function TComplexVariantType.IsClear(const V: TVarData): Boolean;
begin
Result := (TComplexVarData(V).VComplex = nil) or
TComplexVarData(V).VComplex.IsZero;
end;
```

3.2.4.10.7 Copying Data from One Stream to Another

When copying data from one stream to another, you do not need to explicitly read and then write the data. Instead, you can use the *CopyFrom* method, as illustrated in the following example.

In the following example, one file is copied to another one using streams. The application includes two edit controls (*EdFrom* and *EdTo*) and a *Copy File* button.

```
procedure TForm1.CopyFileClick(Sender: TObject);
var
Source, Destination:TStream;
begin
Source := TFileStream.Create(edFrom.Text, fmOpenRead or fmShareDenyWrite);
try
Destination := TFileStream.Create(edTo.Text, fmOpenCreate or fmShareDenyRead);
try
Destination.CopyFrom(Source,Source.Size);
    finally
Destination.Free;
    end;
  finally
    Source.Free
end;
void __fastcall TForm1::CopyFileClick(TObject *Sender)
{
TStream* Source= new TFileStream(edFrom->Text, fmOpenRead | fmShareDenyWrite);
try
  {
    TStream* Destination = new TFileStream(edTo->Text, fmCreate | fmShareDenyRead);
try
    {
      Destination -> CopyFrom(Source, Source->Size);
    }
    __finally
    {
      delete Destination;
    }
  }
  __finally
  {
    delete Source;
  }
}
```

3.2.4.10.8 Creating a Class to Enable the Custom Variant Type

Custom variants work by using a special helper class that indicates how variants of the custom type can perform standard operations. You create this helper class by writing a descendant of TCustomVariantType. This involves overriding the appropriate virtual methods of *TCustomVariantType*.

The following topics provide details on how to implement and use a TCustomVariantType descendant:

- Enabling casting (see page 2097)

- Implementing binary operations (see page 2100)
- Implementing comparison operations (see page 2102)
- Implementing unary operations (see page 2103)
- Copying and clearing custom variants (see page 2093)
- Loading and saving custom variant values (see page 2104)
- Using the TCustomVariantType descendant (see page 2116)

Supporting Properties and Methods in Custom Variants (see page 2108)

3.2.4.10.9 Creating a Simple Conversion Family and Adding Units

One example of when you could create a new conversion family and add new measurement types might be when performing conversions between long periods of time (such as months to centuries) where a loss of precision can occur.

To explain this further, the *cbTime* family uses a day as its base unit. The base unit is the one that is used when performing all conversions within that family. Therefore, all conversions must be done in terms of days. An inaccuracy can occur when performing conversions using units of months or larger (months, years, decades, centuries, millennia) because there is not an exact conversion between days and months, days and years, and so on. Months have different lengths; years have correction factors for leap years, leap seconds, and so on.

If you are only using units of measurement greater than or equal to months, you can create a more accurate conversion family with years as its base unit. This example creates a new conversion family called *cbLongTime*.

Declare variables

First, you need to declare variables for the identifiers. The identifiers are used in the new LongTime conversion family, and the units of measurement that are its members:

```
var
cbLongTime: TConvFamily;
ltMonths: TConvType;
ltYears: TConvType;
ltDecades: TConvType;
ltCenturies: TConvType;
ltMillennia: TConvType;
tConvFamily cbLongTime;
TConvType ltMonths;
TConvType ltYears;
TConvType ltDecades;
TConvType ltCenturies;
TConvType ltMillennia;
```

Register the conversion family

Next, register the conversion family:

```
cbLongTime := RegisterConversionFamily ('Long Times');
cbLongTime = RegisterConversionFamily ("Long Times");
```

Although an *UnregisterConversionFamily* procedure is provided, you don't need to unregister conversion families unless the unit that defines them is removed at runtime. They are automatically cleaned up when your application shuts down.

Register measurement units

Next, you need to register the measurement units within the conversion family that you just created. You use the *RegisterConversionType* function, which registers units of measurement within a specified family. You need to define the base unit which in the example is years, and the other units are defined using a factor that indicates their relation to the base unit. So, the factor for *ltMonths* is 1/12 because the base unit for the LongTime family is years. You also include a description of the units to which you are converting.

The code to register the measurement units is shown here:

```
ltMonths:=RegisterConversionType(cbLongTime,'Months',1/12);
ltYears:=RegisterConversionType(cbLongTime,'Years',1);
ltDecades:=RegisterConversionType(cbLongTime,'Decades',10);
ltCenturies:=RegisterConversionType(cbLongTime,'Centuries',100);
ltMillennia:=RegisterConversionType(cbLongTime,'Millennia',1000);
ltMonths = RegisterConversionType(cbLongTime,"Months",1/12);
ltYears = RegisterConversionType(cbLongTime,"Years",1);
ltDecades = RegisterConversionType(cbLongTime,"Decades",10);
ltCenturies = RegisterConversionType(cbLongTime,"Centuries",100);
ltMillennia = RegisterConversionType(cbLongTime,"Millennia",1000);
```

Use the new units

You can now use the newly registered units to perform conversions. The global *Convert* function can convert between any of the conversion types that you registered with the *cbLongTime* conversion family.

So instead of using the following *Convert* call,

```
Convert(StrToFloat(Edit1.Text),tuMonths,tuMillennia);
Convert(StrToFloat(Edit1->Text),tuMonths,tuMillennia);
```

you can now use this one for greater accuracy:

```
Convert(StrToFloat(Edit1.Text),ltMonths,ltMillennia);
Convert(StrToFloat(Edit1->Text),ltMonths,ltMillennia);
```

See Also

Performing Conversions (see page 2105)

3.2.4.10.10 Defining Custom Variants

One powerful built-in type of the Delphi language is the Variant type. Variants represent values whose type is not determined at compile time. Instead, the type of their value can change at runtime. Variants can mix with other variants and with integer, real, string, and boolean values in expressions and assignments; the compiler automatically performs type conversions.

By default, variants can't hold values that are records, sets, static arrays, files, classes, class references, or pointers. You can, however, extend the Variant type to work with any particular example of these types. All you need to do is create a descendant of the *TCustomVariantType* class that indicates how the Variant type performs standard operations.

To create a Variant type:

1. Map the storage of the variant's data (see page 2107) on to the *TVarData* record.
2. Declare a class that descends from TCustomVariantType (see page 2094). Implement all required behavior (including type conversion rules) in the new class.
3. Write utility methods (see page 2117) for creating instances of your custom variant and recognizing its type.

The above steps extend the Variant type so that the standard operators work with your new type and the new Variant type can be cast to other data types. You can further enhance your new Variant type so that it supports properties and methods that you define. When creating a Variant type that supports properties or methods (see page 2108), you use *TInvokeableVariantType* or *TPublishableVariantType* as a base class rather than *TCustomVariantType*.

3.2.4.10.11 Enabling Casting

One of the most important features of the custom variant type for you to implement is typecasting. The flexibility of variants arises, in part, from their implicit typecasts.

There are two methods for you to implement that enable the custom Variant type to perform typecasts: Cast, which converts another variant type to your custom variant, and CastTo, which converts your custom Variant type to another type of Variant.

When implementing either of these methods, it is relatively easy to perform the logical conversions from the built-in variant types. You must consider, however, the possibility that the variant to or from which you are casting may be another custom Variant type. To handle this situation, you can try casting to one of the built-in Variant types as an intermediate step.

For example, the following *Cast* method, from the *TComplexVariantType* class uses the type Double as an intermediate type:

```
procedure TComplexVariantType.Cast(var Dest: TVarData; const Source: TVarData);
var
LSource, LTemp: TVarData;
begin
VarDataInit(LSource);
try
VarDataCopyNoInd(LSource, Source);
if VarDataIsStr(LSource) then
TComplexVarData(Dest).VComplex := TComplexData.Create(VarDataToStr(LSource))
else
begin
VarDataInit(LTemp);
try
VarDataCastTo(LTemp, LSource, varDouble);
TComplexVarData(Dest).VComplex := TComplexData.Create(LTemp.VDouble, 0);
finally
VarDataClear(LTemp);
end;
end;
Dest.VType := VarType;
finally
VarDataClear(LSource);
end;
end;
```

In addition to the use of Double as an intermediate Variant type, there are a few things to note in this implementation:

- The last step of this method sets the *VType* member of the returned *TVarData* record. This member gives the Variant type code. It is set to the VarType property of *TComplexVariantType*, which is the Variant type code assigned to the custom variant.
- The custom variant's data (*Dest*) is typecast from *TVarData* to the record type that is actually used to store its data (see page 2107) (*TComplexVarData*). This makes the data easier to work with.
- The method makes a local copy of the source variant rather than working directly with its data. This prevents side effects that may affect the source data.

When casting from a complex variant to another type, the *CastTo* method also uses an intermediate type of Double (for any destination type other than a string):

```
procedure TComplexVariantType.CastTo(var Dest: TVarData; const Source: TVarData;
const AVarType: TVarType);
var
LTemp: TVarData;
begin
if Source.VType = VarType then
case AVarType of
varOleStr:
VarDataFromOleStr(Dest, TComplexVarData(Source).VComplex.AsString);
varString:
VarDataFromStr(Dest, TComplexVarData(Source).VComplex.AsString);
else
VarDataInit(LTemp);
try
LTemp.VType := varDouble;
LTemp.VDouble := TComplexVarData(LTemp).VComplex.Real;
VarDataCastTo(Dest, LTemp, AVarType);
finally
VarDataClear(LTemp);
end;
end
else
RaiseCastError;
end;
```

Note that the *CastTo* method includes a case where the source variant data does not have a type code that matches the *VarType* property. This case only occurs for empty (unassigned) source variants.

3.2.4.10.12 Use __fastcall When Overriding VCL Methods

Member functions for VCL classes generally use __fastcall in their declaration unless declared otherwise. This means that you must use __fastcall in the declaration of any VCL class member function that you override.

See Also

__fastcall (see page 530)

__msfastcall (see page 526)

3.2.4.10.13 Working with ini Files and the System Registry

Many applications use ini files to store configuration information. The VCL/RTL includes two classes for working with ini files: *TIniFile* and *TMemIniFile*. Using ini files has the advantage that they can be used in cross-platform applications and they are easy to read and edit. For information on these classes, see Using TIniFile and TMemIniFile (see page 2131) for more information.

Many Windows applications replace the use of ini files with the system Registry. The Windows system Registry is a hierarchical database that acts as a centralized storage space for configuration information. The VCL includes classes for working with the system Registry. Two of these classes, *TRegistryIniFile* and *TRegistry,* are discussed here because of their similarity to the classes for working with ini files.

TRegistryIniFile is useful for cross-platform applications, because it shares a common ancestor (*TCustomIniFile*) with the classes that work with ini files. If you confine yourself to the methods of the common ancestor (*TCustomIniFile*) your application can work on both applications with a minimum of conditional code. *TRegistryIniFile* is discussed in Using TRegistryIniFile (see page 2130).

For applications that are not cross-platform, you can use the *TRegistry* class. The properties and methods of *TRegistry* have names that correspond more directly to the way the system Registry is organized, because it does not need to be compatible with the classes for ini files. *TRegistry* is discussed in Using TRegistry (see page 2099).

Using Streams (see page 2099)

Working with Files (see page 2142)

Working with Strings (see page 2142)

Working with String Lists (see page 2140)

3.2.4.10.14 Using Streams

Streams are classes that let you read and write data. They provide a common interface for reading and writing to different media such as memory, strings, sockets, and BLOB fields in databases. There are several stream classes, which all descend from *TStream*. Each stream class is specific to one media type. For example, *TMemoryStream* reads from or writes to a memory image; *TFileStream* reads from or writes to a file.

The following topics describe the methods common to all stream classes:

- Using streams to read or write data (see page 2115)
- Copying data from one stream to another (see page 2094)
- Specifying the stream position and size (see page 2106)

See Also

TStream

Working with Files (see page 2142)

Using File Streams (see page 2133)

3.2.4.10.15 Using TRegistry

If you are writing a Windows-only application and are comfortable with the structure of the system Registry, you can use

TRegistry. Unlike *TRegistryIniFile*, which uses the same properties and methods of other ini file components, the properties and methods of *TRegistry* correspond more directly to the structure of the system Registry. You can specify both the root key and subkey using *TRegistry*, while *TRegistryIniFile* uses `HKEY_CURRENT_USER` as the root key.

In addition to methods for opening, closing, saving, moving, copying, and deleting keys, *TRegistry* lets you specify the access level you want to use.

Note: *TRegistry* is not available for cross-platform programming.

The following example retrieves a value from a registry entry:

```
function GetRegistryValue(KeyName: string): string;
var
  Registry: TRegistry;
begin
Registry := TRegistry.Create(KEY_READ);
  try
    Registry.RootKey = HKEY_LOCAL_MACHINE;
// False because we do not want to create it if it doesn't exist
    Registry.OpenKey(KeyName, False);
    Result := Registry.ReadString('VALUE1');
  finally
    Registry.Free;
  end;
end;
#include <Registry.hpp>
AnsiString GetRegistryValue(AnsiString KeyName)
{
AnsiString S;
TRegistry *Registry = new TRegistry(KEY_READ);
try
{
Registry->RootKey = HKEY_LOCAL_MACHINE;
// False because we do not want to create it if it doesn't exist
Registry->OpenKey(KeyName,false);
S = Registry->ReadString("VALUE1");
}
__finally
{
delete Registry;
}
return S;
}
```

See Also

Using TRegistryIniFile (see page 2130)

3.2.4.10.16 Implementing Binary Operations

To allow the custom variant type to work with standard binary operators (+, -, *, /, div, mod, shl, shr, and, or, xor listed in the System unit), you must override the BinaryOp method. *BinaryOp* has three parameters: the value of the left-hand operand, the value of the right-hand operand, and the operator. Implement this method to perform the operation and return the result using the same variable that contained the left-hand operand.

For example, the following *BinaryOp* method comes from the *TComplexVariantType* defined in the VarCmplx unit:

```
procedure TComplexVariantType.BinaryOp(var Left: TVarData; const Right: TVarData;
  const Operator: TVarOp);
begin
  if Right.VType = VarType then
    case Left.VType of
      varString:
        case Operator of
```

```
          opAdd: Variant(Left) := Variant(Left) + TComplexVarData(Right).VComplex.AsString;
        else
          RaiseInvalidOp;
        end;
      else
        if Left.VType = VarType then
          case Operator of
            opAdd:
              TComplexVarData(Left).VComplex.DoAdd(TComplexVarData(Right).VComplex);
            opSubtract:
              TComplexVarData(Left).VComplex.DoSubtract(TComplexVarData(Right).VComplex);
            opMultiply:
              TComplexVarData(Left).VComplex.DoMultiply(TComplexVarData(Right).VComplex);
            opDivide:
              TComplexVarData(Left).VComplex.DoDivide(TComplexVarData(Right).VComplex);
            else
              RaiseInvalidOp;
          end
        else
          RaiseInvalidOp;
    end
  else
    RaiseInvalidOp;
end;
```

There are several things to note in this implementation:

This method only handles the case where the variant on the right side of the operator is a custom variant that represents a complex number. If the left-hand operand is a complex variant and the right-hand operand is not, the complex variant forces the right-hand operand first to be cast to a complex variant. It does this by overriding the RightPromotion method so that it always requires the type in the *VarType* property:

```
function TComplexVariantType.RightPromotion(const V: TVarData;
const Operator: TVarOp; out RequiredVarType: TVarType): Boolean;
begin
{ Complex Op TypeX }
RequiredVarType := VarType;
Result := True;
end;
```

The addition operator is implemented for a string and a complex number (by casting the complex value to a string and concatenating), and the addition, subtraction, multiplication, and division operators are implemented for two complex numbers using the methods of the *TComplexData* object that is stored in the complex variant's data. This is accessed by casting the *TVarData* record to a *TComplexVarData* record and using its *VComplex* member.

Attempting any other operator or combination of types causes the method to call the *RaiseInvalidOp* method, which causes a runtime error. The *TCustomVariantType* class includes a number of utility methods such as *RaiseInvalidOp* that can be used in the implementation of custom variant types.

BinaryOp only deals with a limited number of types: strings and other complex variants. It is possible, however, to perform operations between complex numbers and other numeric types. For the *BinaryOp* method to work, the operands must be cast to complex variants before the values are passed to this method. We have already seen (above) how to use the *RightPromotion* method to force the right-hand operand to be a complex variant if the left-hand operand is complex. A similar method, LeftPromotion, forces a cast of the left-hand operand when the right-hand operand is complex:

```
function TComplexVariantType.LeftPromotion(const V: TVarData;
const Operator: TVarOp; out RequiredVarType: TVarType): Boolean;
begin
{ TypeX Op Complex }
if (Operator = opAdd) and VarDataIsStr(V) then
RequiredVarType := varString
else
RequiredVarType := VarType;
  Result := True;
```

```
end;
```

This *LeftPromotion* method forces the left-hand operand to be cast to another complex variant, unless it is a string and the operation is addition, in which case *LeftPromotion* allows the operand to remain a string.

See Also

Implementing Comparison Operations (see page 2102)

Implementing Unary Operations (see page 2103)

Enabling Casting (see page 2097)

Copying and Clearing Custom Variants (see page 2093)

Using the TCustomVariantType Descendant (see page 2116)

Loading and Saving Custom Variant Values (see page 2104)

3.2.4.10.17 Implementing Comparison Operations

There are two ways to enable a custom variant type to support comparison operators (=, <>, <, <=, >, >=). You can override the *Compare* method, or you can override the *CompareOp* method.

The Compare method is easiest if your custom variant type supports the full range of comparison operators. *Compare* takes three parameters: the left-hand operand, the right-hand operand, and a var Parameter that returns the relationship between the two. For example, the *TConvertVariantType* object in the VarConv unit implements the following *Compare* method:

```
procedure TConvertVariantType.Compare(const Left, Right: TVarData;
var Relationship: TVarCompareResult);
const
CRelationshipToRelationship: array [TValueRelationship] of TVarCompareResult =
(crLessThan, crEqual, crGreaterThan);
var
LValue: Double;
LType: TConvType;
LRelationship: TValueRelationship;
begin
// supports...
//   convvar cmp number
//     Compare the value of convvar and the given number
  //   convvar1 cmp convvar2
//     Compare after converting convvar2 to convvar1's unit type
  //  The right can also be a string.  If the string has unit info then it is
//    treated like a varConvert else it is treated as a double
LRelationship := EqualsValue;
case Right.VType of
    varString:
      if TryStrToConvUnit(Variant(Right), LValue, LType) then
        if LType = CIllegalConvType then
          LRelationship := CompareValue(TConvertVarData(Left).VValue, LValue)
        else
          LRelationship := ConvUnitCompareValue(TConvertVarData(Left).VValue,
                                                TConvertVarData(Left).VConvType, LValue, LType)
        else
          RaiseCastError;
    varDouble:
      LRelationship := CompareValue(TConvertVarData(Left).VValue, TVarData(Right).VDouble);
    else
      if Left.VType = VarType then
        LRelationship := ConvUnitCompareValue(TConvertVarData(Left).VValue,
                         TConvertVarData(Left).VConvType, TConvertVarData(Right).VValue,
                         TConvertVarData(Right).VConvType)
      else
        RaiseInvalidOp;
```

```
  end;
  Relationship := CRelationshipToRelationship[LRelationship];
end;
```

If the custom type does not support the concept of "greater than" or "less than," only "equal" or "not equal," however, it is difficult to implement the *Compare* method, because *Compare* must return *crLessThan*, *crEqual*, or *crGreaterThan*. When the only valid response is "not equal," it is impossible to know whether to return *crLessThan* or *crGreaterThan*. Thus, for types that do not support the concept of ordering, you can override the *CompareOp* method instead.

CompareOp has three parameters: the value of the left-hand operand, the value of the right-hand operand, and the comparison operator. Implement this method to perform the operation and return a boolean that indicates whether the comparison is *True*. You can then call the *RaiseInvalidOp* method when the comparison makes no sense.

For example, the following *CompareOp* method comes from the *TComplexVariantType* object in the VarCmplx unit. It supports only a test of equality or inequality:

```
function TComplexVariantType.CompareOp(const Left, Right: TVarData;
const Operator: Integer): Boolean;
begin
Result := False;
if (Left.VType = VarType) and (Right.VType = VarType) then
case Operator of
opCmpEQ:
Result := TComplexVarData(Left).VComplex.Equal(TComplexVarData(Right).VComplex);
opCmpNE:
Result := not TComplexVarData(Left).VComplex.Equal(TComplexVarData(Right).VComplex);
else
RaiseInvalidOp;
end
else
RaiseInvalidOp;
end;
```

Note that the types of operands that both these implementations support are very limited. As with binary operations (see page 2100), you can use the *RightPromotion* and *LeftPromotion* methods to limit the cases you must consider by forcing a cast before *Compare* or *CompareOp* is called.

Loading and Saving Custom Variant Values (see page 2104)

3.2.4.10.18 Implementing Unary Operations

To allow the custom variant type to work with standard unary operators (-, not), you must override the UnaryOp method. *UnaryOp* has two parameters: the value of the operand and the operator. Implement this method to perform the operation and return the result using the same variable that contained the operand.

For example, the following *UnaryOp* method comes from the *TComplexVariantType* defined in the VarCmplx unit:

```
procedure TComplexVariantType.UnaryOp(var Right: TVarData; const Operator: TVarOp);
begin
if Right.VType = VarType then
case Operator of
```

```
opNegate:
TComplexVarData(Right).VComplex.DoNegate;
else
RaiseInvalidOp;
end
else
RaiseInvalidOp;
end;
```

Note that for the logical **not** operator, which does not make sense for complex values, this method calls *RaiseInvalidOp* to cause a runtime error.

Loading and Saving Custom Variant Values (see page 2104)

3.2.4.10.19 Loading and Saving Custom Variant Values

By default, when the custom variant is assigned as the value of a published property, it is typecast to a string when that property is saved to a form file, and converted back from a string when the property is read from a form file. You can, however, provide your own mechanism for loading and saving custom variant values in a more natural representation. To do so, the *TCustomVariantType* descendant must implement the IVarStreamable interface from Classes.pas.

IVarStreamable defines two methods, *StreamIn* and *StreamOut*, for reading a variant's value from a stream and for writing the variant's value to the stream. For example, *TComplexVariantType*, in the VarCmplx unit, implements the *IVarStreamable* methods as follows:

```
procedure TComplexVariantType.StreamIn(var Dest: TVarData; const Stream: TStream);
begin
with TReader.Create(Stream, 1024) do
try
with TComplexVarData(Dest) do
begin
VComplex := TComplexData.Create;
VComplex.Real := ReadFloat;
VComplex.Imaginary := ReadFloat;
end;
finally
Free;
end;
end;
procedure TComplexVariantType.StreamOut(const Source: TVarData; const Stream: TStream);
begin
with TWriter.Create(Stream, 1024) do
try
with TComplexVarData(Source).VComplex do
begin
WriteFloat(Real);
WriteFloat(Imaginary);
end;
finally
Free;
end;
end;
```

Note how these methods create a Reader or Writer object for the *Stream* parameter to handle the details of reading or writing values.

3.2.4.10.20 Performing Conversions

You can use the *Convert* function to perform both simple and complex conversions. It includes a simple syntax and a second syntax for performing conversions between complex measurement types.

Performing simple conversions

You can use the *Convert* function to convert a measurement from one set of units to another. The *Convert* function converts between units that measure the same type of thing (distance, area, time, temperature, and so on).

To use *Convert*, you must specify the units from which to convert and to which to convert. You use the TConvType type to identify the units of measurement.

For example, this converts a temperature from degrees Fahrenheit to degrees Kelvin:

```
TempInKelvin := Convert(StrToFloat(Edit1.Text), tuFahrenheit, tuKelvin);
TempInKelvin = Convert(StrToFloat(Edit1->Text), tuFahrenheit, tuKelvin);
```

Performing complex conversions

You can also use the *Convert* function to perform more complex conversions between the ratio of two measurement types. Examples of when you might need to use this this are when converting miles per hour to meters per minute for calculating speed or when converting gallons per minute to liters per hour for calculating flow.

For example, the following call converts miles per gallon to kilometers per liter:

```
nKPL := Convert(StrToFloat(Edit1.Text), duMiles, vuGallons, duKilometers, vuLiter);
double nKPL = Convert(StrToFloat(Edit1.Text), duMiles, vuGallons, duKilometers, vuLiter);
```

The units you're converting must be in the same conversion family (they must measure the same thing). If the units are not compatible, *Convert* raises an *EConversionError* exception. You can check whether two *TConvType* values are in the same conversion family by calling CompatibleConversionTypes.

The StdConvs unit defines several families of *TConvType* values.

3.2.4.10.21 Persistent Lists

Persistent lists can be saved to a form file. Because of this, they are often used as the type of a published property on a component. You can add items to the list at design time, and those items are saved with the object so that they are there when the component that uses them is loaded into memory at runtime. There are two main types of persistent lists: string lists and collections.

Examples of string lists include *TStringList* and *THashedStringList*. String lists, as the name implies, contain strings. They provide special support for strings of the form Name=Value, so that you can look up the value associated with a name. In

addition, most string lists let you associate an object with each string in the list. String lists are described in more detail in Working with string lists (see page 2140).

Collections descend from the class *TCollection*. Each *TCollection* descendant is specialized to manage a specific class of items, where that class descends from *TCollectionItem*. Collections support many of the common list operations (see page 2091). All collections are designed to be the type of a published property, and many can not function independently of the object that uses them to implement on of its properties. At design time, the property whose value is a collection can use the collection editor to let you add, remove, and rearrange items. The collection editor provides a common user interface for manipulating collections.

3.2.4.10.22 Specifying the Stream Position and Size

In addition to methods for reading and writing, streams permit applications to seek to an arbitrary position in the stream or change the size of the stream. Once you seek to a specified position, the next read or write operation starts reading from or writing to the stream at that position.

Seeking to a specific position

The *Seek* method is the most general mechanism for moving to a particular position in the stream. There are two overloads for the *Seek* method:

```
function Seek(Offset: Longint; Origin: Word): Longint;
function Seek(const Offset: Int64; Origin: TSeekOrigin): Int64;
virtual int __fastcall Seek(int Offset, Word Origin);
virtual __int64 __fastcall Seek(const __int64 Offset, TSeekOrigin Origin);
```

Both overloads work the same way. The difference is that one version uses a 32-bit integer to represent positions and offsets, while the other uses a 64-bit integer.

The *Origin* parameter indicates how to interpret the *Offset* parameter. *Origin* should be one of the following values:

Values for the Origin parameter

Value	Meaning
soFromBeginning	Offset is from the beginning of the resource. Seek moves to the position Offset. Offset must be >= 0.
soFromCurrent	Offset is from the current position in the resource. Seek moves to Position + Offset.
soFromEnd	Offset is from the end of the resource. Offset must be <= 0 to indicate a number of bytes before the end of the file.

Seek resets the current stream position, moving it by the indicated offset. *Seek* returns the new current position in the stream.

Using Position and Size properties

All streams have properties that hold the current position and size of the stream. These are used by the *Seek* method, as well as all the methods that read from or write to the stream.

The *Position* property indicates the current offset, in bytes, into the stream (from the beginning of the streamed data). The declaration for *Position* is:

```
property Position: Int64;
__property __int64 Position = {read=GetPosition, write=SetPosition, nodefault};
```

The *Size* property indicates the size of the stream in bytes. It can be used to determine the number of bytes available for reading, or to truncate the data in the stream. The declaration for *Size* is:

```
property Size: Int64;
__property __int64 Size = {read=GetSize, write=SetSize64, nodefault};
```

Size is used internally by routines that read and write to and from the stream.

Setting the *Size* property changes the size of the data in the stream. For example, on a file stream, setting *Size* inserts an end of file marker to truncate the file. If the *Size* of the stream cannot be changed, an exception is raised. For example, trying to change the *Size* of a read-only file stream raises an exception.

Copying Data from One Stream to Another (see page 2094)

3.2.4.10.23 Storing a Custom Variant Type's Data

Variants store their data in the *TVarData* record type. This type is a record that contains 16 bytes. The first word indicates the type of the variant, and the remaining 14 bytes are available to store the data. While your new Variant type can work directly with a *TVarData* record, it is usually easier to define a record type whose members have names that are meaningful for your new type, and cast that new type onto the *TVarData* record type.

For example, the VarConv unit defines a custom variant type that represents a measurement. The data for this type includes the units (*TConvType*) of measurement, as well as the value (a double). The VarConv unit defines its own type to represent such a value:

```
TConvertVarData = packed record
  VType: TVarType;
  VConvType: TConvType;
  Reserved1, Reserved2: Word;
  VValue: Double;
end;
```

This type is exactly the same size as the *TVarData* record. When working with a custom variant of the new type, the variant (or its *TVarData* record) can be cast to *TConvertVarData*, and the custom Variant type simply works with the *TVarData* record as if it were a *TConvertVarData* type.

Note: When defining a record that maps onto the *TVarData* record in this way, be sure to define it as a packed record.

If your new custom Variant type needs more than 14 bytes to store its data, you can define a new record type that includes a pointer or object instance. For example, the VarCmplx unit uses an instance of the class *TComplexData* to represent the data in a complex-valued variant. It therefore defines a record type the same size as *TVarData* that includes a reference to a *TComplexData* object:

```
TComplexVarData = packed record
  VType: TVarType;
  Reserved1, Reserved2, Reserved3: Word;
  VComplex: TComplexData;
  Reserved4: LongInt;
end;
```

Object references are actually pointers (two Words), so this type is the same size as the *TVarData* record. As before, a complex custom variant (or its *TVarData* record), can be cast to *TComplexVarData*, and the custom variant type works with the *TVarData* record as if it were a *TComplexVarData* type.

3.2.4.10.24 String Dependencies

Sometimes you need to convert a long string to a null-terminated string, for example, if you are using a function that takes a *PChar*. If you must cast a string to a *PChar*, be aware that you are responsible for the lifetime of the resulting *PChar*. Because long strings are reference counted, typecasting a string to a *PChar* increases the dependency on the string by one, without actually incrementing the reference count. When the reference count hits zero, the string will be destroyed, even though there is an extra dependency on it. The cast *PChar* will also disappear, while the routine you passed it to may still be using it. For example:

```
procedure my_func(x: string);
begin
  // do something with x
  some_proc(PChar(x)); // cast the string to a PChar
  // you now need to guarantee that the string remains
  // as long as the some_proc procedure needs to use it
end;
```

Returning a PChar Local Variable (see page 2131)

Passing a Local Variable as a PChar (see page 2128)

3.2.4.10.25 Supporting Properties and Methods in Custom Variants

Some variants have properties and methods. For example, when the value of a variant is an interface, you can use the variant to read or write the values of properties on that interface and call its methods. Even if your custom variant type does not represent an interface, you may want to give it properties and methods that an application can use in the same way.

Using TInvokeableVariantType

To provide support for properties and methods, the class you create to enable the new custom variant type (see page 2094) should descend from TInvokeableVariantType instead of directly from *TCustomVariantType*.

TInvokeableVariantType defines four methods:

- DoFunction
- DoProcedure
- GetProperty
- SetProperty

that you can implement to support properties and methods on your custom variant type.

For example, the VarConv unit uses *TInvokeableVariantType* as the base class for *TConvertVariantType* so that the resulting custom variants can support properties. The following example shows the property getter for these properties:

```
function TConvertVariantType.GetProperty(var Dest: TVarData;
const V: TVarData; const Name: String): Boolean;
var
LType: TConvType;
begin
// supports...
//   'Value'
//   'Type'
//   'TypeName'
//   'Family'
//   'FamilyName'
//   'As[Type]'
Result := True;
if Name = 'VALUE' then
```

```
Variant(Dest) := TConvertVarData(V).VValue
else if Name = 'TYPE' then
Variant(Dest) := TConvertVarData(V).VConvType
else if Name = 'TYPENAME' then
Variant(Dest) := ConvTypeToDescription(TConvertVarData(V).VConvType)
else if Name = 'FAMILY' then
Variant(Dest) := ConvTypeToFamily(TConvertVarData(V).VConvType)
else if Name = 'FAMILYNAME' then
Variant(Dest) := ConvFamilyToDescription(ConvTypeToFamily(TConvertVarData(V).VConvType))
else if System.Copy(Name, 1, 2) = 'AS' then
begin
if DescriptionToConvType(ConvTypeToFamily(TConvertVarData(V).VConvType),
System.Copy(Name, 3, MaxInt), LType) then
VarConvertCreateInto(Variant(Dest), Convert(TConvertVarData(V).VValue,
TConvertVarData(V).VConvType, LType), LType)
else
Result := False;
end
else
Result := False;
end;
```

The *GetProperty* method checks the *Name* parameter to determine what property is wanted. It then retrieves the information from the *TVarData* record of the Variant (*V*), and returns it as a Variant (*Dest*). Note that this method supports properties whose names are dynamically generated at runtime (As[Type]), based on the current value of the custom variant.

Similarly, the *SetProperty*, *DoFunction*, and *DoProcedure* methods are sufficiently generic that you can dynamically generate method names, or respond to variable numbers and types of parameters.

Using TPublishableVariantType

If the custom variant type stores its data using an object instance, then there is an easier way to implement properties, as long as they are also properties of the object that represents the variant's data. If you use TPublishableVariantType as the base class for your custom variant type, then you need only implement the GetInstance method, and all the published properties of the object that represents the variant's data are automatically implemented for the custom variants.

For example, as was seen in Storing a custom variant type's data (see page 2107), *TComplexVariantType* stores the data of a complex-valued variant using an instance of *TComplexData*. *TComplexData* has a number of published properties (*Real*, *Imaginary*, *Radius*, *Theta*, and *FixedTheta*), that provide information about the complex value. *TComplexVariantType* descends from *TPublishableVariantType*, and implements the *GetInstance* method to return the *TComplexData* object (in TypInfo.pas) that is stored in a complex-valued variant's *TVarData* record:

```
function TComplexVariantType.GetInstance(const V: TVarData): TObject;
begin
Result := TComplexVarData(V).VComplex;
end;
```

TPublishableVariantType does the rest. It overrides the *GetProperty* and *SetProperty* methods to use the runtime type information (RTTI) of the *TComplexData* object for getting and setting property values.

Note: For *TPublishableVariantType* to work, the object that holds the custom variant's data must be compiled with RTTI. This means it must be compiled using the {$M+} compiler directive, or descend from *TPersistent*.

3.2.4.10.26 Using a Class to Manage Conversions

You can always use conversion functions to register a conversion unit. There are times, however, when this requires you to create an unnecessarily large number of functions that all do essentially the same thing.

If you can write a set of conversion functions that differ only in the value of a parameter or variable, you can create a class to handle those conversions. For example, there is a set standard techniques for converting between the various European currencies since the introduction of the Euro. Even though the conversion factors remain constant (unlike the conversion factor between, say, dollars and Euros), you can't use a simple conversion factor approach to properly convert between European currencies for two reasons:

- The conversion must round to a currency-specific number of digits.
- The conversion factor approach uses an inverse factor to the one specified by the standard Euro conversions.

However, this can all be handled by the conversion functions such as the following:

```
function FromEuro(const AValue: Double, Factor; FRound: TRoundToRange): Double;
begin
Result := RoundTo(AValue * Factor, FRound);
end;
function ToEuro(const AValue: Double, Factor): Double;
begin
Result := AValue / Factor;
end;
double __fastcall FromEuro(const double AValue, const double Factor, TRoundToRange FRound)
{
return(RoundTo(AValue * Factor, FRound));
}
double __fastcall ToEuro(const double AValue, const double Factor)
{
return (AValue / Factor);
}
```

The problem is, this approach requires extra parameters on the conversion function, which means you can't simply register the same function with every European currency. In order to avoid having to write two new conversion functions for every European currency, you can make use of the same two functions by making them the members of a class.

Creating the conversion class

The class must be a descendant of *TConvTypeFactor*. *TConvTypeFactor* defines two methods, *ToCommon* and *FromCommon*, for converting to and from the base units of a conversion family (in this case, to and from Euros). Just as with the functions you use directly when registering a conversion unit, these methods have no extra parameters, so you must supply the number of digits to round off and the conversion factor as private members of your conversion class:

```
type
TConvTypeEuroFactor = class(TConvTypeFactor)
private
FRound: TRoundToRange;
public
constructor Create(const AConvFamily: TConvFamily;
const ADescription: string; const AFactor: Double;
const ARound: TRoundToRange);
function ToCommon(const AValue: Double): Double; override;
function FromCommon(const AValue: Double): Double; override;
end;
end;
class PASCALIMPLEMENTATION TConvTypeEuroFactor : public Convutils::TConvTypeFactor
{
  private:
TRoundToRange FRound;
public:
    __fastcall TConvTypeEuroFactor(const TConvFamily AConvFamily,
```

```
        const AnsiString ADescription, const double AFactor, const TRoundToRange ARound);
              TConvTypeFactor(AConvFamily, ADescription, AFactor);
    virtual double ToCommon(const double AValue);
virtual double FromCommon(const double AValue);
}
```

The constructor assigns values to those private members:

```
constructor TConvTypeEuroFactor.Create(const AConvFamily: TConvFamily;
const ADescription: string; const AFactor: Double;
const ARound: TRoundToRange);
begin
inherited Create(AConvFamily, ADescription, AFactor);
FRound := ARound;
end;
__fastcall TConvTypeEuroFactor::TConvTypeEuroFactor(const TConvFamily AConvFamily,
        const AnsiString ADescription, const double AFactor, const TRoundToRange ARound):
              TConvTypeFactor(AConvFamily, ADescription, AFactor);
{
  FRound = ARound;
}
```

The two conversion functions simply use these private members:

```
function TConvTypeEuroFactor.FromCommon(const AValue: Double): Double;
begin
Result := RoundTo(AValue * Factor, FRound);
end;
function TConvTypeEuroFactor.ToCommon(const AValue: Double): Double;
begin
Result := AValue / Factor;
end;
virtual double TConvTypeEuroFactor::ToCommon(const double AValue)
{
  return (RoundTo(AValue * Factor, FRound));
}
virtual double TConvTypeEuroFactor::ToCommon(const double AValue)
{
  return (AValue / Factor);
}
```

Declare variables

Now that you have a conversion class, begin as with any other conversion family, by declaring identifiers:

```
var
  euEUR: TConvType; { EU euro }
euBEF: TConvType; { Belgian francs }
euDEM: TConvType; { German marks }
euGRD: TConvType; { Greek drachmas }
euESP: TConvType; { Spanish pesetas }
euFFR: TConvType; { French francs }
euIEP: TConvType; { Irish pounds }
euITL: TConvType; { Italian lire }
euLUF: TConvType; { Luxembourg francs }
euNLG: TConvType; { Dutch guilders }
euATS: TConvType; { Austrian schillings }
euPTE: TConvType; { Portuguese escudos }
euFIM: TConvType; { Finnish marks }
  cbEuro: TConvFamily;
TConvFamily cbEuro;
TConvType euEUR; // EU euro
TConvType euBEF; // Belgian francs
TConvType euDEM; // German marks
TConvType euGRD; // Greek drachmas
TConvType euESP; // Spanish pesetas
TConvType euFFR; // French francs
TConvType euIEP; // Irish pounds
```

```
TConvType euITL; // Italian lire
TConvType euLUF; // Luxembourg francs
TConvType euNLG; // Dutch guilders
TConvType euATS; // Austrian schillings
TConvType euPTE; // Protuguese escudos
TConvType euFIM; // Finnish marks
```

Register the conversion family and the other units

Now you are ready to register the conversion family and the European monetary units, using your new conversion class. Register the conversion family the same way you registered the other conversion families:

```
cbEuro := RegisterConversionFamily ('European currency');
cbEuro = RegisterConversionFamily ("European currency");
```

To register each conversion type, create an instance of the conversion class that reflects the factor and rounding properties of that currency, and call the RegisterConversionType method:

```
var
  LInfo: TConvTypeInfo;
begin
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'EUEuro', 1.0, -2);
  if not RegisterConversionType(LInfo, euEUR) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'BelgianFrancs', 40.3399, 0);
  if not RegisterConversionType(LInfo, euBEF) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'GermanMarks', 1.95583, -2);
  if not RegisterConversionType(LInfo, euDEM) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'GreekDrachmas', 340.75, 0);
  if not RegisterConversionType(LInfo, euGRD) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'SpanishPesetas', 166.386, 0);
  if not RegisterConversionType(LInfo, euESP) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'FrenchFrancs', 6.55957, -2);
  if not RegisterConversionType(LInfo, euFFR) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'IrishPounds', 0.787564, -2);
  if not RegisterConversionType(LInfo, euIEP) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'ItalianLire', 1936.27, 0);
  if not RegisterConversionType(LInfo, euITL) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'LuxembourgFrancs', 40.3399, -2);
  if not RegisterConversionType(LInfo, euLUF) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'DutchGuilders', 2.20371, -2);
  if not RegisterConversionType(LInfo, euNLG) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'AustrianSchillings', 13.7603, -2);
  if not RegisterConversionType(LInfo, euATS) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'PortugueseEscudos', 200.482, -2);
  if not RegisterConversionType(LInfo, euPTE) then
    LInfo.Free;
  LInfo := TConvTypeEuroFactor.Create(cbEuro, 'FinnishMarks', 5.94573, 0);
  if not RegisterConversionType(LInfo, euFIM) then
    LInfo.Free;
end;
TConvTypeInfo *pInfo = new TConvTypeEuroFactor(cbEuro, "EUEuro", 1.0, -2);
if (!RegisterConversionType(pInfo, euEUR))
  delete pInfo;
pInfo = new TConvTypeEuroFactor(cbEuro, "BelgianFrancs", 40.3399, 0);
if (!RegisterConversionType(pInfo, euBEF))
  delete pInfo;
```

```
pInfo = new TConvTypeEuroFactor(cbEuro, "GermanMarks", 1.95583, -2);
if (!RegisterConversionType(pInfo, euDEM))
  delete pInfo;
pInfo = new TConvTypeEuroFactor(cbEuro, "GreekDrachmas", 340.75, 0);
if (!RegisterConversionType(pInfo, euGRD)
  delete pInfo;
pInfo = new TConvTypeEuroFactor(cbEuro, "SpanishPesetas", 166.386, 0);
if (!RegisterConversionType(pInfo, euESP)
  delete pInfo;
pInfo = new TConvTypeEuroFactor(cbEuro, "FrenchFrancs", 6.55957, -2);
if (!RegisterConversionType(pInfo, euFFR)
  delete pInfo;
pInfo = new TConvTypeEuroFactor(cbEuro, "IrishPounds", 0.787564, -2);
if (!RegisterConversionType(pInfo, euIEP)
  delete pInfo;
pInfo = new TConvTypeEuroFactor(cbEuro, "ItalianLire", 1936.27, 0);
if (!RegisterConversionType(pInfo, euITL)
  delete pInfo;
pInfo = new TConvTypeEuroFactor(cbEuro, "LuxembourgFrancs", 40.3399, -2);
if (!RegisterConversionType(pInfo, euLUF)
  delete pInfo;
pInfo = new TConvTypeEuroFactor(cbEuro, "DutchGuilders", 2.20371, -2);
if (!RegisterConversionType(pInfo, euNLG)
  delete pInfo;
pInfo = new TConvTypeEuroFactor(cbEuro, "AutstrianSchillings", 13.7603, -2);
if (!RegisterConversionType(pInfo, euATS)
  delete pInfo;
pInfo = new TConvTypeEuroFactor(cbEuro, "PortugueseEscudos", 200.482, -2);
if (!RegisterConversionType(pInfo, euPTE)
  delete pInfo;
pInfo = new TConvTypeEuroFactor(cbEuro, "FinnishMarks", 5.94573, 0);
if (!RegisterConversionType(pInfo, euFIM)
  delete pInfo;
```

Note: The ConvertIt demo provides an expanded version of this example that includes other currencies (that do not have fixed conversion rates) and more error checking.

Use the new units

You can now use the newly registered units to perform conversions in your applications. The global *Convert* function can convert between any of the European currencies you have registered with the new cbEuro family. For example, the following code converts a value from Italian Lire to German Marks:

```
Edit2.Text = FloatToStr(Convert(StrToFloat(Edit1.Text), euITL, euDEM));
Edit2->Text = FloatToStr(Convert(StrToFloat(Edit1->Text), euITL, euDEM));
```

See Also

Performing Conversions (see page 2105)

3.2.4.10.27 Using a Conversion Function

For cases when the conversion is more complex, you can use a different syntax to specify a function to perform the conversion instead of using a conversion factor. For example, you can't convert temperature values using a conversion factor, because different temperature scales have a different origins.

This example, which comes from the StdConvs unit, shows how to register a conversion type by providing functions to convert to and from the base units.

Declare variables

First, declare variables for the identifiers. The identifiers are used in the *cbTemperature* conversion family, and the units of measurement are its members:

```
var
cbTemperature: TConvFamily;
tuCelsius: TConvType;
tuKelvin: TConvType;
tuFahrenheit: TConvType;
TConvFamily cbTemperature;
TConvType tuCelsius;
TConvType tuKelvin;
TConvType tuFahrenheit;
```

Note: The units of measurement listed here are a subset of the temperature units actually registered in the *StdConvs* unit.

Register the conversion family

Next, register the conversion family:

```
cbTemperature := RegisterConversionFamily ('Temperature');
cbTemperature = RegisterConversionFamily ("Temperature");
```

Register the base unit

Next, define and register the base unit of the conversion family, which in the example is degrees Celsius. Note that in the case of the base unit, we can use a simple conversion factor, because there is no actual conversion to make:

```
tuCelsius:=RegisterConversionType(cbTemperature,'Celsius',1);
tuCelsius = RegisterConversionType(cbTemperature,"Celsius",1);
```

Write methods to convert to and from the base unit

You need to write the code that performs the conversion from each temperature scale to and from degrees Celsius, because these do not rely on a simple conversion factor. These functions are taken from the StdConvs unit:

```
function FahrenheitToCelsius(const AValue: Double): Double;
begin
Result := ((AValue - 32) * 5) / 9;
end;
function CelsiusToFahrenheit(const AValue: Double): Double;
begin
Result := ((AValue * 9) / 5) + 32;
end;
function KelvinToCelsius(const AValue: Double): Double;
begin
Result := AValue - 273.15;
end;
function CelsiusToKelvin(const AValue: Double): Double;
begin
Result := AValue + 273.15;
end;
double __fastcall FahrenheitToCelsius(const double AValue)
{
return (((AValue - 32) * 5) / 9);
}
double __fastcall CelsiusToFahrenheit(const double AValue)
{
return (((AValue * 9) / 5) + 32);
}
double __fastcall KelvinToCelsius(const double AValue)
{
  return (AValue - 273.15);
}
double __fastcall CelsiusToKelvin(const double AValue)
{
  return (AValue + 273.15);
}
```

Register the other units

Now that you have the conversion functions, you can register the other measurement units within the conversion family. You also

include a description of the units.

The code to register the other units in the family is shown here:

```
tuKelvin := RegisterConversionType(cbTemperature, 'Kelvin', KelvinToCelsius, CelsiusToKelvin);
tuFahrenheit := RegisterConversionType(cbTemperature, 'Fahrenheit', FahrenheitToCelsius,
CelsiusToFahrenheit);
tuKelvin = RegisterConversionType(cbTemperature, "Kelvin", KelvinToCelsius, CelsiusToKelvin);
tuFahrenheit = RegisterConversionType(cbTemperature, "Fahrenheit", FahrenheitToCelsius,
CelsiusToFahrenheit);
```

Use the new units

You can now use the newly registered units to perform conversions in your applications. The global *Convert* function can convert between any of the conversion types that you registered with the *cbTemperature* conversion family. For example the following code converts a value from degrees Fahrenheit to degrees Kelvin.

```
Convert(StrToFloat(Edit1.Text), tuFahrenheit, tuKelvin);
Convert(StrToFloat(Edit1->Text), tuFahrenheit, tuKelvin);
```

3.2.4.10.28 Using Streams to Read or Write Data

Stream classes all share several methods for reading and writing data. These methods are distinguished by whether they:

- Return the number of bytes read or written.
- Require the number of bytes to be known.
- Raise an exception on error.

Stream methods for reading and writing

The *Read* method reads a specified number of bytes from the stream, starting at its current *Position*, into a buffer. *Read* then advances the current position by the number of bytes actually transferred. The prototype for *Read* is:

```
function Read(var Buffer; Count: Longint): Longint;
virtual int __fastcall Read(void *Buffer, int Count);
```

Read is useful when the number of bytes in the file is not known. *Read* returns the number of bytes actually transferred, which may be less than *Count* if the stream did not contain *Count* bytes of data past the current position.

The *Write* method writes *Count* bytes from a buffer to the stream, starting at the current *Position*. The prototype for *Write* is:

```
function Write(const Buffer; Count: Longint): Longint;
virtual int __fastcall Write(const void *Buffer, int Count);
```

After writing to the file, *Write* advances the current position by the number bytes written, and returns the number of bytes actually written, which may be less than *Count* if the end of the buffer is encountered or the stream can't accept any more bytes.

The counterpart procedures are *ReadBuffer* and *WriteBuffer* which, unlike *Read* and *Write*, do not return the number of bytes read or written. These procedures are useful in cases where the number of bytes is known and required, for example when reading in structures. *ReadBuffer* and *WriteBuffer* raise an exception (*EReadError* and *EWriteError*) if the byte count can not be matched exactly. This is in contrast to the *Read* and *Write* methods, which can return a byte count that differs from the requested value. The prototypes for *ReadBuffer* and *WriteBuffer* are:

```
procedure ReadBuffer(var Buffer; Count: Longint);
procedure WriteBuffer(const Buffer; Count: Longint);
virtual int __fastcall ReadBuffer(void *Buffer, int Count);
virtual int __fastcall WriteBuffer(const void *Buffer, int Count);
```

These methods call the *Read* and *Write* methods to perform the actual reading and writing.

Reading and writing components

TStream defines specialized methods, ReadComponent and WriteComponent, for reading and writing components. You can use them in your applications as a way to save components and their properties when you create or alter them at runtime.

ReadComponent and *WriteComponent* are the methods that the IDE uses to read components from or write them to form files. When streaming components to or from a form file, stream classes work with the *TFiler* classes, *TReader* and *TWriter*, to read objects from the form file or write them out to disk. For more information about using the component streaming system, see TStream, TFiler, TReader, TWriter, and TComponent classes.

Reading and writing strings

If you are passing a string to a read or write function, you need to be aware of the correct syntax. The *Buffer* parameters for the read and write routines are **var** and **const** types, respectively. These are untyped parameters, so the routine takes the address of a variable.

The most commonly used type when working with strings is a long string. However, passing a long string as the *Buffer* parameter does not produce the correct result. Long strings contain a size, a reference count, and a pointer to the characters in the string. Consequently, dereferencing a long string does not result in the pointer element. You need to first cast the string to a *Pointer* or *PChar*, and then dereference it. For example:

```
procedure caststring;
var
  fs: TFileStream;
const
  s: string = 'Hello';
begin
  fs := TFileStream.Create('temp.txt', fmCreate or fmOpenWrite);
  fs.Write(s, Length(s));// this will give you garbage
  fs.Write(PChar(s)^, Length(s));// this is the correct way
end;
```

3.2.4.10.29 Using the TCustomVariantType Descendant

In the initialization section of the unit that defines your *TCustomVariantType* descendant, create an instance of your class. When you instantiate your object, it automatically registers itself with the variant-handling system so that the new Variant type is enabled. For example, here is the initialization section of the VarCmplx unit:

```
initialization
ComplexVariantType := TComplexVariantType.Create;
```

In the finalization section of the unit that defines your *TCustomVariantType* descendant, free the instance of your class. This automatically unregisters the variant type. Here is the finalization section of the VarCmplx unit:

```
finalization
FreeAndNil(ComplexVariantType);
```

3.2.4.10.30 Writing Utilities to Work with a Custom Variant Type

Once you have created a *TCustomVariantType* descendant to implement your custom variant type, it is possible to use the new Variant type in applications. However, without a few utilities, this is not as easy as it should be.

It is a good idea to create a method that creates an instance of your custom variant type from an appropriate value or set of values. This function or set of functions fills out the structure you defined (see page 2107) to store your custom variant's data. For example, the following function could be used to create a complex-valued variant:

```
function VarComplexCreate(const AReal, AImaginary: Double): Variant;
begin
  VarClear(Result);
TComplexVarData(Result).VType := ComplexVariantType.VarType;
TComplexVarData(ADest).VComplex := TComplexData.Create(ARead, AImaginary);
end;
```

This function does not actually exist in the VarCmplx unit, but is a synthesis of methods that do exist, provided to simplify the example. Note that the returned variant is cast to the record that was defined to map onto the *TVarData* structure (*TComplexVarData*), and then filled out.

Another useful utility to create is one that returns the variant type code for your new Variant type. This type code is not a constant. It is automatically generated when you instantiate your *TCustomVariantType* descendant. It is therefore useful to provide a way to easily determine the type code for your custom variant type. The following function from the VarCmplx unit illustrates how to write one, by simply returning the *VarType* property of the *TCustomVariantType* descendant:

```
function VarComplex: TVarType;
begin
Result := ComplexVariantType.VarType;
end;
```

Two other standard utilities provided for most custom variants check whether a given variant is of the custom type and cast an arbitrary variant to the new custom type. Here is the implementation of those utilities from the VarCmplx unit:

```
function VarIsComplex(const AValue: Variant): Boolean;
begin
Result := (TVarData(AValue).VType and varTypeMask) = VarComplex;
end;
function VarAsComplex(const AValue: Variant): Variant;
begin
if not VarIsComplex(AValue) then
VarCast(Result, AValue, VarComplex)
else
Result := AValue;
end;
```

Note that these use standard features of all variants: the *VType* member of the *TVarData* record and the *VarCast* function, which works because of the methods implemented in the TCustomVariantType descendant for casting data (see page 2097).

In addition to the standard utilities mentioned above, you can write any number of utilities specific to your new custom variant type. For example, the VarCmplx unit defines a large number of functions that implement mathematical operations on complex-valued variants.

3.2.4.10.31 Commonly Used Long String Routines

The string handling routines in `SysUtils` handle both **UnicodeString** and **AnsiString** types. Within their functional areas, some routines are used for the same purpose, the differences being whether they use a particular criterion in their calculations.

The `AnsiStrings` unit's functions offer the same capabilities as the `SysUtils` unit's routines. `AnsiStrings` functions provide better performance for **AnsiString** than `SysUtils` functions, because `SysUtils` functions convert an **AnsiString** to a **UnicodeString**. `AnsiStrings` functions work only with **AnsiString**, so there is no conversion.

The following tables list these routines by these functional areas:

- Comparison
- Case conversion
- Modification
- Sub-string

Where appropriate, the tables also provide columns indicating whether a routine satisfies the following criteria.

- Uses case sensitivity: If locale settings are used, it determines the definition of case. If the routine does not use locale settings, analyses are based upon the ordinal values of the characters. If the routine is case-insensitive, there is a logical merging of upper and lower case characters that is determined by a predefined pattern.
- Uses locale settings: Locale settings allow you to customize your application for specific locales, in particular, for Asian language environments. Most locale settings consider lowercase characters to be less than the corresponding uppercase characters. This is in contrast to ASCII order, in which lowercase characters are greater than uppercase characters. Routines that use the system locale are typically prefaced with Ansi (that is, AnsiXXX).
- Supports the multi-byte character set (MBCS): MBCSs are used when writing code for far eastern locales. Multi-byte characters are represented by one or more character codes, so the length in bytes does not necessarily correspond to the length of the string. The routines that support MBCS parse one- and multibyte characters.

ByteType and *StrByteType* determine whether a particular byte is the lead byte of a multibyte character. Be careful when using multibyte characters not to truncate a string by cutting a character in half. Do not pass characters as a parameter to a function or procedure, since the size of a character cannot be predetermined. Pass, instead, a pointer to a to a character or string. For more information about MBCS, see Enabling Application Code (see page 1924).

String length routines:

Routine	Uses locale settings	Supports MBCS	Returns
System.Length	yes	yes	Number of *elements* in string. Does not account for MBCS or Unicode surrogate pair "characters".
System.SizeOf	yes	yes	Number of *bytes* required to represent type or variable.

Note that `Length` and `SizeOf` give different results for all strings except for short strings. `SizeOf` equals the number of bytes in a pointer, since non-short strings are pointers.

String comparison routines:

Routine	Case-sensitive	Uses locale settings	Supports MBCS
AnsiStrings.AnsiCompareStr SysUtils.AnsiCompareStr	yes	yes	yes
AnsiStrings.AnsiCompareText SysUtils.AnsiCompareText	no	yes	yes

AnsiStrings.AnsiCompareFileName SysUtils.AnsiCompareFileName	no	yes	yes
AnsiStrings.AnsiMatchStr StrUtils.AnsiMatchStr	yes	yes	yes
AnsiStrings.AnsiMatchText StrUtils.AnsiMatchText	no	yes	yes
AnsiStrings.AnsiContainsStr StrUtils.AnsiContainsStr	yes	yes	yes
AnsiStrings.AnsiContainsText StrUtils.AnsiContainsText	no	yes	yes
AnsiStrings.AnsiStartsStr StrUtils.AnsiStartsStr	yes	yes	yes
AnsiStrings.AnsiStartsText StrUtils.AnsiStartsText	no	yes	yes
AnsiStrings.AnsiEndsStr StrUtils.AnsiEndsStr	yes	yes	yes
AnsiStrings.AnsiEndsText StrUtils.AnsiEndsText	no	yes	yes
AnsiStrings.AnsiEndsStr StrUtils.AnsiEndsStr	yes	yes	yes
AnsiStrings.AnsiIndexText StrUtils.AnsiIndexText	no	yes	yes
AnsiStrings.CompareStr SysUtils.CompareStr	yes	no	no
AnsiStrings.CompareText SysUtils.CompareText	no	no	no
StrUtils.AnsiResemblesText	no	no	no

Case conversion routines:

Routine	Uses locale settings	Supports MBCS
AnsiStrings.AnsiLowerCase SysUtils.AnsiLowerCase	yes	yes
AnsiStrings.AnsiUpperCaseFileName SysUtils.AnsiUpperCaseFileName	yes	yes
AnsiStrings.AnsiUpperCase SysUtils.AnsiUpperCase	yes	yes
AnsiStrings.LowerCase SysUtils.LowerCase	no	no. Works for A to Z only, not European accented characters.
AnsiStrings.UpperCase SysUtils.UpperCase	no	no. Works for a to z only, not European accented characters.

Note: The routines used for string file names: *AnsiCompareFileName*, *AnsiLowerCaseFileName*, and *AnsiUpperCaseFileName* all use the system locale. You should always use file names that are portable because the locale (character set) used for file names can and might differ from the default user interface.

String modification routines:

Routine	Case-sensitive	Supports MBCS
SysUtils.AdjustLineBreaks	NA	yes
AnsiStrings.AnsiQuotedStr SysUtils.AnsiQuotedStr	NA	yes
AnsiStrings.AnsiReplaceStr StrUtils.AnsiReplaceStr	yes	yes
AnsiStrings.AnsiReplaceText StrUtils.AnsiReplaceText	no	yes
AnsiStrings.StringReplace SysUtils.StringReplace	optional by flag	yes
AnsiStrings.ReverseString StrUtils.ReverseString	NA	no
AnsiStrings.StuffString StrUtils.StuffString	NA	no
System.FillChar	NA	no
SysUtils.StrPCopy	yes	yes
AnsiStrings.Trim SysUtils.Trim	NA	yes
AnsiStrings.TrimLeft SysUtils.TrimLeft	NA	yes
AnsiStrings.TrimRight SysUtils.TrimRight	NA	yes
SysUtils.WrapText	NA	yes

Sub-string routines:

Routine	Case-sensitive	Supports MBCS
SysUtils.AnsiExtractQuotedStr	NA	yes
AnsiStrings.AnsiPos SysUtils.AnsiPos	yes	yes
AnsiStrings.IsDelimiter SysUtils.IsDelimiter	yes	yes
AnsiStrings.IsPathDelimiter SysUtils.IsPathDelimiter	yes	yes
AnsiStrings.LastDelimiter SysUtils.LastDelimiter	yes	yes
StrUtils.LeftStr	NA	no

StrUtils.RightStr	NA	no
StrUtils.MidStr	NA	no
AnsiStrings.QuotedStr SysUtils.QuotedStr	no	no
System.StringOfChar	NA	yes

String information routines (in System):

Routine	Returns
System.StringCodePage	Code page
System.StringElementSize	Element size
System.StringRefCount	Reference count

Note: It is not safe to directly manipulate the internal structures of strings, since these change with product versions.

3.2.4.10.32 Commonly Used Routines for Null-terminated Strings

The null-terminated string handling routines cover several functional areas. Within these areas, some are used for the same purpose, the differences being whether or not they use a particular criteria in their calculations. The following tables list these routines by these functional areas:

- Comparison
- Case conversion
- Modification
- Sub-string
- Copying

Where appropriate, the tables also provide columns indicating whether the routine is case-sensitive, uses the current locale, and/or supports multi-byte character sets.

Null-terminated string comparison routines

Routine	Case-sensitive	Uses locale settings	Supports MBCS
SysUtils.AnsiStrComp	yes	yes	yes
SysUtils.AnsiStrIComp	no	yes	yes
SysUtils.AnsiStrLComp	yes	yes	yes
SysUtils.AnsiStrLIComp	no	yes	yes
SysUtils.StrComp	yes	no	no
SysUtils.StrIComp	no	no	no
SysUtils.StrLComp	yes	no	no

SysUtils.StrLIComp	no	no	no

Null-terminated case conversion routines

Routine	Uses locale settings	Supports MBCS
SysUtils.AnsiStrLower	yes	yes
SysUtils.AnsiStrUpper	yes	yes
SysUtils.StrLower	no	no
SysUtils.StrUpper	no	no

String modification routines

Routine
SysUtils.StrCat
SysUtils.StrLCat

3.2.4.10.33 Compiler Directives for Strings

The following compiler directives affect character and string types.

Compiler directives for strings

Directive	Description
{$H+/-}	A compiler directive, $H, controls whether the reserved word **string** represents a short string or a long string. In the default state, {$H+}, **string** represents a long string. You can change it to a *ShortString* by using the {$H-} directive.
{$P+/-}	The $P directive is meaningful only for code compiled in the {$H-} state, and is provided for backwards compatibility. $P controls the meaning of variable parameters declared using the string keyword in the {$H-} state. In the {$P-} state, variable parameters declared using the string keyword are normal variable parameters, but in the {$P+} state, they are open string parameters. Regardless of the setting of the $P directive, the OpenString identifier can always be used to declare open string parameters.
{$V+/-}	The $V directive controls type checking on short strings passed as variable parameters. In the {$V+} state, strict type checking is performed, requiring the formal and actual parameters to be of identical string types. In the {$V-} (relaxed) state, any short string type variable is allowed as an actual parameter, even if the declared maximum length is not the same as that of the formal parameter. Be aware that this could lead to memory corruption. For example: var S: string[3]; procedure Test(var T: string); begin T := '1234'; end; begin Test(S); end.
{$X+/-}	The {$X+} compiler directive enables support for null-terminated strings by activating the special rules that apply to the built-in PChar type and zero-based character arrays. (These rules allow zero-based arrays and character pointers to be used with *Write*, *Writeln*, *Val*, *Assign*, and *Rename* from the System unit.)

Declaring and Initializing Strings (see page 2123)

3.2.4.10.34 Copying a File

The runtime library does not provide any routines for copying a file. However, if you are writing Windows-only applications, you can directly call the Windows API *CopyFile* function to copy a file. Like most of the runtime library file routines, *CopyFile* takes a filename as a parameter, not a file handle. When copying a file, be aware that the file attributes for the existing file are copied to the new file, but the security attributes are not. *CopyFile* is also useful when moving files across drives because neither the *RenameFile* function nor the Windows API *MoveFile* function can rename or move files across drives.

Deleting a File (see page 2124)

3.2.4.10.35 Declaring and Initializing Strings

When you declare a string:

```
S: string;
```

you do not need to initialize it. Strings are automatically initialized to empty. To test a string for empty you can either use the *EmptyStr* variable:

```
S = EmptyStr;
```

or test against an empty string:

```
S = '';
```

An empty string has no valid data. Therefore, trying to index an empty string is like trying to access **nil** and will result in an access violation:

```
var
  S: string;
begin
  S[i];    // this will cause an access violation
  // statements
end;
```

Similarly, if you cast an empty string to a *PChar*, the result is a **nil** pointer. So, if you are passing such a *PChar* to a routine that needs to read or write to it, be sure that the routine can handle **nil**:

```
var
  S: string;   // empty string
begin
  proc(PChar(S));  // be sure that proc can handle nil
  // statements
end;
```

If it cannot, then you can either initialize the string:

```
  S := 'No longer nil';
  proc(PChar(S));// proc does not need to handle nil now
```

or set the length, using the *SetLength* procedure:

```
  SetLength(S, 100);//sets the dynamic length of S to 100 characters
  proc(PChar(S));// proc does not need to handle nil now
```

When you use *SetLength*, existing characters in the string are preserved, but the contents of any newly allocated space is undefined. Following a call to *SetLength*, S is guaranteed to reference a unique string, that is a string with a reference count of one.

String literals are Unicode by default. To initialize a string to ANSI characters, cast the literal:

```
AnsiString S;
S := AnsiString('Unicode string');
```

To obtain the length of a string in *elements*, use the `Length` function. Note that for MBCS and Unicode strings, this is not necessarily the number of characters.

To obtain the length of a short string in *bytes*, use the `SizeOf` function. For the other string types, multiply `Length` by `SizeOf`. For instance, if S is a **UnicodeString**, its length in bytes is `Length(S) * SizeOf(S)`.

Remember when declaring a **string** that:

```
  S: string[n];
```

implicitly declares a short string, not a string of *n* length. To declare a string of specifically *n* length, declare a variable of type **string** and use the *SetLength* procedure.

```
  S: string;
  SetLength(S, n);
```

Unicode in RAD Studio

3.2.4.10.36 Deleting a File

Deleting a file erases the file from the disk and removes the entry from the disk's directory. There is no corresponding operation to restore a deleted file, so applications should generally allow users to confirm before deleting files. To delete a file, pass the name of the file to the *DeleteFile* function:

```
DeleteFile(FileName);
```

DeleteFile returns *True* if it deleted the file and *False* if it did not (for example, if the file did not exist or if it was read-only). *DeleteFile* erases the file named by *FileName* from the disk.

File Date-time Routines (see page 2125)

Copying a File (see page 2123)

3.2.4.10.37 File Date-time Routines

The *FileAge*, *FileGetDate*, and *FileSetDate* routines operate on operating system date-time values. *FileAge* returns the date-and-time stamp of a file, or -1 if the file does not exist. *FileSetDate* sets the date-and-time stamp for a specified file, and returns zero on success or an error code on failure. *FileGetDate* returns a date-and-time stamp for the specified file or –1 if the handle is invalid.

As with most of the file manipulating routines, *FileAge* uses a string filename. *FileGetDate* and *FileSetDate*, however, use a *Handle* type as a parameter. To get the file handle either:

- Use the *FileOpen* or *FileCreate* function to create a new file or open an existing file. Both *FileOpen* and *FileCreate* return the file handle.
- Instantiate *TFileStream* to create or open a file. Then use its *Handle* property. See Using file streams (see page 2133) for more information.

Renaming a File (see page 2130)

Deleting a File (see page 2124)

Copying a File (see page 2123)

3.2.4.10.38 Finding a File

There are three routines used for finding a file: *FindFirst*, *FindNext*, and *FindClose*. *FindFirst* searches for the first instance of a filename with a given set of attributes in a specified directory. *FindNext* returns the next entry matching the name and attributes specified in a previous call to *FindFirst*. *FindClose* releases memory allocated by *FindFirst*. You should always use *FindClose* to terminate a *FindFirst*/*FindNext* sequence. If you want to know if a file exists, a *FileExists* function returns *True* if the file exists, *False* otherwise.

The three file find routines take a *TSearchRec* as one of the parameters. *TSearchRec* defines the file information searched for by *FindFirst* or *FindNext*. If a file is found, the fields of the *TSearchRec* type parameter are modified to describe the found file.

```
type
  TFileName = string;
  TSearchRec = record
    Time: Integer;//Time contains the time stamp of the file.
    Size: Integer;//Size contains the size of the file in bytes.
    Attr: Integer;//Attr represents the file attributes of the file.
    Name: TFileName;//Name contains the filename and extension.
    ExcludeAttr: Integer;
    FindHandle: THandle;
    FindData: TWin32FindData;//FindData contains additional information such as
```

```
    //file creation time, last access time, long and short filenames.
  end;
struct TSearchRec
{
int Time; // time stamp of the file
int Size; // size of the file in bytes
int Attr; // file attribute flags
AnsiString Name; // filename and extension
int ExcludeAttr; // file attribute flags for files to ignore
unsigned FindHandle;
_WIN32_FIND_DATAA FindData; // structure with addition information
} ;
```

On field of *TSearchRec* that is of particular interest is the *Attr* field. You can test *Attr* against the following attribute constants or values to determine if a file has a specific attribute:

Attribute constants and values

Constant	Value	Description
faReadOnly	$00000001	Read-only files
faHidden	$00000002	Hidden files
faSysFile	$00000004	System files
faVolumeID	$00000008	Volume ID files
faDirectory	$00000010	Directory files
faArchive	$00000020	Archive files
faAnyFile	$0000003F	Any file

To test for an attribute, combine the value of the *Attr* field with the attribute constant using the **and** operator. If the file has that attribute, the result will be greater than 0. For example, if the found file is a hidden file, the following expression will evaluate to *True*:

```
(SearchRec.Attr and faHidden > 0).
(SearchRec.Attr & faHidden > 0).
```

Attributes can be combined by OR'ing their constants or values. For example, to search for read-only and hidden files in addition to normal files, pass the following as the *Attr* parameter.

```
(faReadOnly or faHidden).
(faReadOnly | faHidden).
```

The following example illustrates the use of the three file find routines. It uses a label, a button named *Search*, and a button named *Again* on a form. When the user clicks the *Search* button, the first file in the specified path is found, and the name and the number of bytes in the file appear in the label's caption. Each time the user clicks the *Again* button, the next matching filename and size is displayed in the label:

```
var
  SearchRec: TSearchRec;
procedure TForm1.SearchClick(Sender: TObject);
begin
  FindFirst('c:\Program Files\MyProgram\bin\

*.*', faAnyFile, SearchRec);
  Label1.Caption := SearchRec.Name + ' is ' + IntToStr(SearchRec.Size) + " bytes in size';
end;
procedure TForm1.AgainClick(Sender: TObject);
begin
  if FindNext(SearchRec) = 0 then
    Label1.Caption := SearchRec.Name + ' is ' + IntToStr(SearchRec.Size) + ' bytes in size'
  else
    FindClose(SearchRec);
```

```
end;
  TSearchRec SearchRec; // global variable
void __fastcall TForm1::SearchClick(TObject *Sender)
{
  FindFirst("c:\\Program Files\\MyProgram\\bin\\
*.*", faAnyFile, SearchRec);
  Label1->Caption = SearchRec->Name + " is " + IntToStr(SearchRec.Size) + " bytes in size";
}
void __fastcall TForm1::AgainClick(TObject *Sender)
{
  if (FindNext(SearchRec) == 0)
    Label1->Caption = SearchRec->Name + " is " + IntToStr(SearchRec.Size) + " bytes in size";
  else
    FindClose(SearchRec);
}
```

Note: In cross-platform applications, you should replace any hard-coded pathnames with the correct pathname for the system or use environment variables (on the Environment Variables page when you choose Tools->Options->Environment Options

) to represent them.

3.2.4.10.39 Manipulating Files

Several common file operations are built into the runtime library. The routines for working with files operate at a high level. For most routines, you specify the name of the file and the routine makes the necessary calls to the operating system for you. In some cases, you use file handles instead.

Warning: Although the Delphi language is not case sensitive, the Linux operating system is. Be attentive to case when working with files in cross-platform applications.

The following topics describe how to use runtime library routines to perform file manipulation tasks:

- Deleting a file (see page 2124)
- Finding a file (see page 2125)
- Renaming a file (see page 2130)
- File date-time routines (see page 2125)
- Copying a file (see page 2123)

3.2.4.10.40 Mixing and Converting String Types

Short, long, and wide strings can be mixed in assignments and expressions, and the compiler automatically generates code to perform the necessary string type conversions. However, when assigning a string value to a short string variable, be aware that the string value is truncated if it is longer than the declared maximum length of the short string variable.

Long strings are already dynamically allocated. If you use one of the built-in pointer types, such as *PAnsiString*, *PString*, or *PWideString*, remember that you are introducing another level of indirection. Be sure this is what you intend.

See Also

Declaring and Initializing Strings (see page 2123)

3.2.4.10.41 Passing a Local Variable as a PChar

Consider the case where you have a local string variable that you need to initialize by calling a function that takes a *PChar*. One approach is to create a local **array of char** and pass it to the function, then assign that variable to the string:

```
// assume FillBuffer is a predefined function
function FillBuffer(Value:Integer; Buf:PChar; Count:Integer):Integer
begin
  . . .
end;
// assume MAX_SIZE is a predefined constant
var
  i: Integer;
  buf: array[0..MAX_SIZE] of char;
  S: string;
begin
  i := FillBuffer(0, buf, SizeOf(buf));// treats buf as a PChar
  S := buf;
  //statements
end;
```

This approach is useful if the size of the buffer is relatively small, since it is allocated on the stack. It is also safe, since the conversion between an **array of char** and a **string** is automatic. The *Length* of the string is automatically set to the right value after assigning *buf* to the string.

To eliminate the overhead of copying the buffer, you can cast the string to a *PChar* (if you are certain that the routine does not need the *PChar* to remain in memory). However, synchronizing the length of the string does not happen automatically, as it does when you assign an **array of char** to a **string**. You should reset the string *Length* so that it reflects the actual width of the string. If you are using a function that returns the number of bytes copied, you can do this safely with one line of code:

```
var
  S: string;
begin
  SetLength(S, MAX_SIZE);// when casting to a PChar, be sure the string is not empty
  SetLength(S, GetModuleFilename(0, PChar(S), Length(S)));
  // statements
end;
```

String Dependencies (see page 2108)

Returning a PChar Local Variable (see page 2131)

3.2.4.10.42 Creating Drawing Spaces

The *TCanvas* class is defined in the Graphics unit, and encapsulates a Windows device context. This class handles all drawing for forms, visual containers (such as panels) and the printer object (see Printing (see page 2129)). Using the canvas object, you need not worry about allocating pens, brushes, palettes, and so on—all the allocation and deallocation are handled for you.

TCanvas includes a large number of primitive graphics routines to draw lines, shapes, polygons, fonts, etc. onto any control that contains a canvas. For example, here is a button event handler that draws a line from the upper left corner to the middle of the form and outputs some raw text onto the form:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
Canvas.Pen.Color := clBlue;
Canvas.MoveTo( 10, 10 );
Canvas.LineTo( 100, 100 );
Canvas.Brush.Color := clBtnFace;
Canvas.Font.Name := 'Arial';
```

```
Canvas.TextOut( Canvas.PenPos.x, Canvas.PenPos.y,'This is the end of the line' );
end;
void __fastcall TForm1::Button1Click(TObject *Sender)
{
Canvas->Pen->Color = clBlue;
Canvas->MoveTo( 10, 10 );
Canvas->LineTo( 100, 100 );
Canvas->Brush->Color = clBtnFace;
Canvas->Font->Name = "Arial";
Canvas->TextOut( Canvas->PenPos.x, Canvas->PenPos.y,"This is the end of the line" );
}
```

The *TCanvas* object defined in the Graphics unit also protects you against common Windows graphics errors, such as restoring device contexts, pens, brushes, and so on to the value they had before the drawing operation. *TCanvas* is used everywhere in the VCL that drawing is required or possible, and makes drawing graphics both fail-safe and easy.

See Also

Printing (see page 2129)

3.2.4.10.43 Printing

The VCL *TPrinter* object encapsulates details of Windows printers. To get a list of installed and available printers, use the *Printers* property. Both printer objects use a *TCanvas* (which is identical to the form's *TCanvas*) which means that anything that can be drawn on a form can be printed as well. To print an image, call the *BeginDoc* method followed by whatever canvas graphics you want to print (including text through the *TextOut* method) and send the job to the printer by calling the *EndDoc* method.

This example uses a button and a memo on a form. When the user clicks the button, the content of the memo is printed with a 200-pixel border around the page.

To run this example successfully, add Printers to your **uses** clause.

```
procedure TForm1.Button1Click(Sender: TObject);
var
r: TRect;
i: Integer;
begin
with Printer do
begin
r := Rect(200,200,(Pagewidth - 200),(PageHeight - 200));
BeginDoc;
      Canvas.Brush.Style := bsClear;
for i := 0 to Memo1.Lines.Count do
Canvas.TextOut(200,200 + (i *
                  Canvas.TextHeight(Memo1.Lines.Strings[i])),
                  Memo1.Lines.Strings[i]);
Canvas.Brush.Color := clBlack;
Canvas.FrameRect(r);
EndDoc;
end;
end;
void __fastcall TForm1::Button1Click(TObject *Sender)
{
TPrinter *Prntr = Printer();
TRect r = Rect(200,200,Prntr->PageWidth - 200,Prntr->PageHeight- 200);
Prntr->BeginDoc();
for( int i = 0; i < Memo1->Lines->Count; i++)
Prntr->Canvas->TextOut(200,200 + (i *
  Prntr->Canvas->TextHeight(Memo1->Lines->Strings[i])),
  Memo1->Lines->Strings[i]);
Prntr->Canvas->Brush->Color = clBlack;
Prntr->Canvas->FrameRect(r);
```

```
Prntr->EndDoc();
}
```

3.2.4.10.44 Using TRegistryIniFile

Many 32-bit Windows applications store their information in the system Registry instead of ini files because the Registry is hierarchical and doesn't suffer from the size limitations of ini files. If you are accustomed to using ini files and want to move your configuration information to the Registry instead, you can use the *TRegistryIniFile* class. You may also want to use *TRegistryIniFile* in cross-platform applications if you want to use the system Registry on Windows and an ini file on Linux. You can write most of your application so that it uses the *TCustomIniFile* type. You need only conditionalize the code that creates an instance of *TRegistryIniFile* (on Windows) or *TMemIniFile* (on Linux) and assigns it to the *TCustomIniFile* your application uses.

TRegistryIniFile makes Registry entries look like ini file entries. All the methods from *TIniFile* and *TMemIniFile* (read and write) exist in *TRegistryIniFile*.

When you construct a *TRegistryIniFile* object, the parameter you pass to the constructor (corresponding to the filename for an *IniFile* or *TMemIniFile* object) becomes a key value under the user key in the registry. All sections and values branch from that root. *TRegistryIniFile* simplifies the Registry interface considerably, so you may want to use it instead of the *TRegistry* component even if you aren't porting existing code or writing a cross-platform application.

Using TINIFile (see page 2131)

Using TRegistry (see page 2099)

3.2.4.10.45 Renaming a File

To change a file name, use the *RenameFile* function:

```
function RenameFile(const OldFileName, NewFileName: string): Boolean;
extern PACKAGE bool __fastcall RenameFile(const AnsiString OldName, const AnsiString NewName);
```

RenameFile changes a file name, identified by *OldFileName*, to the name specified by *NewFileName*. If the operation succeeds, *RenameFile* returns *True*. If it cannot rename the file (for example, if a file called *NewFileName* already exists), *RenameFile* returns *False*. For example:

```
if not RenameFile('OLDNAME.TXT','NEWNAME.TXT') then
  ErrorMsg('Error renaming file!');
if (!RenameFile("OLDNAME.TXT","NEWNAME.TXT"))
  ErrorMsg("Error renaming file!");
```

You cannot rename (move) a file across drives using *RenameFile*. You would need to first copy the file and then delete the old one.

Note: *RenameFile* in the runtime library is a wrapper around the Windows API *MoveFile* function, so *MoveFile* will not work across drives either.

File Date-time Routines (see page 2125)

Copying a File (see page 2123)

3.2.4.10.46 Returning a PChar Local Variable

A common error when working with *PChars* is to store a local variable in a data structure, or return it as a value. When your routine ends, the *PChar* disappears because it is a pointer to memory, and not a reference counted copy of the string. For example:

```
function title(n: Integer): PChar;
var
  s: string;
begin
  s := Format('title - %d', [n]);
  Result := PChar(s); // DON'T DO THIS
end;
```

This example returns a pointer to string data that is freed when the *title* function returns.

See Also

String Dependencies (see page 2108)

Passing a Local Variable as a PChar (see page 2128)

3.2.4.10.47 String to PChar Conversions

Long string (**AnsiString** and **UnicodeString**) to *PChar* conversions are not automatic. Some of the differences between strings and *PChars* can make conversions problematic:

- Long strings are reference-counted, while *PChars* are not.
- Assigning to a string copies the data, while a *PChar* is a pointer to memory.
- Long strings are null-terminated and also contain the length of the string and other information, while *PChars* are simply null-terminated.

Situations in which these differences can cause subtle errors are discussed in the following topics:

- String dependencies (see page 2108)
- Returning a PChar local variable (see page 2131)
- Passing a local variable as a PChar (see page 2128)

See Also

Declaring and Initializing Strings (see page 2123)

Mixing and Converting String Types (see page 2127)

3.2.4.10.48 Using TIniFile and TMemIniFile

The ini file format is still popular, many configuration files (such as the DSK Desktop settings file) are in this format. This format is especially useful in cross-platform applications, where you can't always count on a system Registry for storing configuration information. The VCL/RTL provides two classes, *TIniFile* and *TMemIniFile*, to make reading and writing ini files very easy.

TIniFile works directly with the ini file on disk while *TMemIniFile* buffers all changes in memory and does not write them to disk until you call the *UpdateFile* method.

When you instantiate the *TIniFile* or *TMemIniFile* object, you pass the name of the ini file as a parameter to the constructor. If the file does not exist, it is automatically created. You are then free to read values using the various read methods, such as *ReadString*, *ReadDate*, *ReadInteger*, or *ReadBool*. Alternatively, if you want to read an entire section of the ini file, you can use the *ReadSection* method. Similarly, you can write values using methods such as *WriteBool*, *WriteInteger*, *WriteDate*, or

WriteString.

Following is an example of reading configuration information from an ini file in a form's *OnCreate* event handler and writing values in the *OnClose* event handler.

```
procedure TForm1.FormCreate(Sender: TObject);
var
  Ini: TIniFile;
begin
  Ini := TIniFile.Create( ChangeFileExt( Application.ExeName, '.INI' ) );
  try
    Top     := Ini.ReadInteger( 'Form', 'Top', 100 );
 Left    := Ini.ReadInteger( 'Form', 'Left', 100 );
 Caption := Ini.ReadString( 'Form', 'Caption', 'New Form' );
    if Ini.ReadBool( 'Form', 'InitMax', false ) then
      WindowState = wsMaximized
    else
      WindowState = wsNormal;
  finally
    TIniFile.Free;
  end;
end;
procedure TForm1.FormClose(Sender: TObject; var Action TCloseAction)
var
  Ini: TIniFile;
begin
  Ini := TIniFile.Create( ChangeFileExt( Application.ExeName, '.INI' ) );
  try
    Ini.WriteInteger( 'Form', 'Top', Top);
    Ini.WriteInteger( 'Form', 'Left', Left);
 Ini.WriteString( 'Form', 'Caption', Caption );
    Ini.WriteBool( 'Form', 'InitMax', WindowState = wsMaximized );
  finally
    TIniFile.Free;
  end;
end;
__fastcall TForm1::TForm1(TComponent *Owner) : TForm(Owner)
{
TIniFile *ini;
ini = new TIniFile( ChangeFileExt( Application->ExeName, ".INI" ) );
Top     =  ini->ReadInteger( "Form", "Top", 100 );
Left    =  ini->ReadInteger( "Form", "Left", 100 );
Caption =  ini->ReadString( "Form", "Caption",
"Default Caption" );
ini->ReadBool( "Form", "InitMax", false ) ?
WindowState = wsMaximized :
WindowState = wsNormal;
delete ini;
}
void __fastcall TForm1::FormClose(TObject *Sender, TCloseAction &Action)
{
TIniFile *ini;
ini = new TIniFile(ChangeFileExt( Application->ExeName, ".INI" ) );
   ini->WriteInteger( "Form", "Top", Top );
ini->WriteInteger( "Form", "Left", Left );
ini->WriteString ( "Form", "Caption", Caption );
ini->WriteBool   ( "Form", "InitMax",
WindowState == wsMaximized );
delete ini;
}
```

Each of the Read routines takes three parameters. The first parameter identifies the section of the ini file. The second parameter identifies the value you want to read, and the third is a default value in case the section or value doesn't exist in the ini file. Just as the Read methods gracefully handle the case when a section or value does not exist, the Write routines create the section and/or value if they do not exist. The example code creates an ini file the first time it is run that looks like this:

```
[Form]
Top=100
Left=100
Caption=Default Caption
InitMax=0
```

On subsequent execution of this application, the ini values are read in when the form is created and written back out in the *OnClose* event.

See Also

Using TRegistryIniFile (see page 2130)

3.2.4.10.49 Using File Streams

The *TFileStream* class enables applications to read from and write to a file on disk. Because *TFileStream* is a stream object, it shares the common stream methods. You can use these methods to read from or write to the file, copy data to or from other stream classes, and read or write components values. See Using streams (see page 2099) for details on the capabilities that files streams inherit by being stream classes.

In addition, file streams give you access to the file handle, so that you can use them with global file handling routines that require the file handle.

Creating and opening files using file streams

To create or open a file and get access to its handle, you simply instantiate a *TFileStream*. This opens or creates a specified file and provides methods to read from or write to it. If the file cannot be opened, the *TFileStream* constructor raises an exception.

```
constructor Create(const filename: string; Mode: Word);
__fastcall TFileStream(const AnsiString FileName, Word Mode);
```

The *Mode* parameter specifies how the file should be opened when creating the file stream. The *Mode* parameter consists of an open mode and a share mode OR'ed together. The open mode must be one of the following values:

Open modes

Value	Meaning
fmCreate	TFileStream a file with the given name. If a file with the given name exists, open the file in write mode.
fmOpenRead	Open the file for reading only.
fmOpenWrite	Open the file for writing only. Writing to the file completely replaces the current contents.
fmOpenReadWrite	Open the file to modify the current contents rather than replace them.

The share mode can be one of the following values with the restrictions listed below:

Share modes

Value	Meaning
fmShareCompat	Sharing is compatible with the way FCBs are opened (VCL applications only).
fmShareExclusive	Other applications can not open the file for any reason.
fmShareDenyWrite	Other applications can open the file for reading but not for writing.
fmShareDenyRead	Other applications can open the file for writing but not for reading (VCL applications only).
fmShareDenyNone	No attempt is made to prevent other applications from reading from or writing to the file.

Note that which share mode you can use depends on which open mode you used. The following table shows shared modes that are available for each open mode.

Shared modes available for each open mode

Open Mode	fmShareCompat (VCL)	fmShareExclusive	fmShareDenyWrite	fmShareDenyRead (VCL)	fmShareDenyNone
fmOpenRead	Can't use	Can't use	Available	Can't use	Available
fmOpenWrite	Available	Available	Can't use	Available	Available
fmOpenReadWrite	Available	Available	Available	Available	Available

The file open and share mode constants are defined in the *SysUtils* unit.

Using the file handle

When you instantiate *TFileStream* you get access to the file handle. The file handle is contained in the *Handle* property. On Windows, *Handle* is a Windows file handle. *Handle* is read-only and reflects the mode in which the file was opened. If you want to change the attributes of the file *Handle*, you must create a new file stream object.

Some file manipulation routines take a file handle as a parameter. Once you have a file stream, you can use the *Handle* property in any situation in which you would use a file handle. Be aware that, unlike handle streams, file streams close file handles when the object is destroyed.

See Also

Using Streams (see page 2099)

3.2.4.10.50 Accessing a Particular String

The *Strings* array property contains the strings in the list, referenced by a zero-based index. Because *Strings* is the default property for string lists, you can omit the *Strings* identifier when accessing the list; thus

```
StringList1.Strings[0] := 'This is the first string.';
StringList1->Strings[0] = "This is the first string.";
```

is equivalent to

```
StringList1[0] := 'This is the first string.';
(*StringList1)[0] = "This is the first string.";
```

See Also

Manipulating Strings in a List (see page 2139)

3.2.4.10.51 Adding a String to a List

To add a string to the end of a string list, call the *Add* method, passing the new string as the parameter. To insert a string into the list, call the *Insert* method, passing two parameters: the string and the index of the position where you want it placed. For example, to make the string "Three" the third string in a list, you would use:

```
Insert(2, 'Three');
StringList1->Insert(2, "Three");
```

To append the strings from one list onto another, call *AddStrings*:

```
StringList1.AddStrings(StringList2);  { append the strings from StringList2 to StringList1 }
StringList1->AddStrings(StringList2);  // append the strings from StringList2 to StringList1
```

See Also

Manipulating Strings in a List (see page 2139)

3.2.4.10.52 Associating Objects with a String List

In addition to the strings stored in its *Strings* property, a string list can maintain references to *objects*, which it stores in its *Objects* property. Like *Strings*, *Objects* is an array with a zero-based index. The most common use for *Objects* is to associate bitmaps with strings for owner-draw controls.

Use the *AddObject* or *InsertObject* method to add a string and an associated object to the list in a single step. *IndexOfObject* returns the index of the first string in the list associated with a specified object. Methods like *Delete*, *Clear*, and *Move* operate on both strings and objects; for example, deleting a string removes the corresponding object (if there is one).

To associate an object with an existing string, assign the object to the *Objects* property at the same index. You cannot add an object without adding a corresponding string.

See Also

Working with String Lists (see page 2140)

3.2.4.10.53 Copying a Complete String List

You can use the *Assign* method to copy strings from a source list to a destination list, overwriting the contents of the destination list. To append strings without overwriting the destination list, use *AddStrings*. For example,

```
Memo1.Lines.Assign(ComboBox1.Items);    { overwrites original strings }
Memo1->Lines->Assign(ComboBox1->Item)s;
```

copies the lines from a combo box into a memo (overwriting the memo), while

```
Memo1.Lines.AddStrings(ComboBox1.Items);   { appends strings to end }
Memo1->Lines->AddStrings(ComboBox1->Items);
```

appends the lines from the combo box to the memo.

When making local copies of a string list, use the *Assign* method. If you assign one string-list variable to another—

```
StringList1 := StringList2;
StringList1 = StringList2;
```

—the original string-list object will be lost, often with unpredictable results.

See Also

Manipulating Strings in a List (see page 2139)

3.2.4.10.54 Counting the Strings in a List

The read-only *Count* property returns the number of strings in the list. Since string lists use zero-based indexes, *Count* is one more than the index of the last string.

See Also

Manipulating Strings in a List (see page 2139)

3.2.4.10.55 Creating a New String List

A string list is typically part of a component. There are times, however, when it is convenient to create independent string lists, for example to store strings for a lookup table. The way you create and manage a string list depends on whether the list is short-term (constructed, used, and destroyed in a single routine) or long-term (available until the application shuts down). Whichever type of string list you create, remember that you are responsible for freeing the list when you finish with it.

Short-term string lists

If you use a string list only for the duration of a single routine, you can create it, use it, and destroy it all in one place. This is the safest way to work with string lists. Because the string-list object allocates memory for itself and its strings, you should use a **try...finally** block to ensure that the memory is freed even if an exception occurs.

To create a short-term string list:

1. Construct the string-list object.
2. In the try part of a **try...finally** block, use the string list.
3. In the finally part, free the string-list object.

The following event handler responds to a button click by constructing a string list, using it, and then destroying it.

```
procedure TForm1.Button1Click(Sender: TObject);
var  TempList: TStrings;{ declare the list }
begin
  TempList := TStringList.Create;{ construct the list object }
  try    { use the string list }
  finally    TempList.Free;{ destroy the list object }
  end;
end;
void __fastcall TForm1::ButtonClick1(TObject *Sender)
{
   TStringList *TempList = new TStringList; // declare the list
   try{
      //use the string list
   }
   __finally{
delete TempList; // destroy the list object
   }
}
```

Long-term string lists

If a string list must be available at any time while your application runs, construct the list at start-up and destroy it before the application terminates.

To create a long-term string list:

1. In the unit file for your application's main form, add a field of type *TStrings* to the form's declaration.
2. Write an event handler for the main form's OnCreate event that executes before the form appears. It should create a string list and assign it to the field you declared in the first step.
3. Write an event handler that frees the string list for the form's *OnClose* event.

This example uses a long-term string list to record the user's mouse clicks on the main form, then saves the list to a file before the application terminates.

```
unit Unit1;
interface
uses Windows, Messages, SysUtils, Variants, Classes, Graphics, Controls, Forms, Dialogs;
type  TForm1 = class(TForm)
    procedure FormCreate(Sender: TObject);
    procedure FormDestroy(Sender: TObject);
    procedure FormMouseDown(Sender: TObject; Button: TMouseButton; Shift: TShiftState; X, Y:
Integer);
  private
    { Private declarations }
  public
    { Public declarations }
    ClickList: TStrings;{ declare the field }
  end;
var  Form1: TForm1;
```

```
implementation
{$R *.DFM}
procedure TForm1.FormCreate(Sender: TObject);
begin
        ClickList := TStringList.Create;{ construct the list }
end;

procedure TForm1.FormDestroy(Sender: TObject);
begin
    ClickList.SaveToFile(ChangeFileExt(Application.ExeName, '.log'));{ save the list }
 ClickList.Free;{ destroy the list object }
end;

procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;  Shift: TShiftState; X,
Y: Integer);
begin
    ClickList.Add(Format('Click at (%d, %d)', [X, Y]));{ add a string to the list }
end;

end.

{
TVarRec v[] = {X,Y};
ClickList->Add(Format("Click at (%d, %d)",v,ARRAYSIZE(v) - 1));//add a string to the list
```

Note: Although you can use events such as OnCreate and OnDestroy to allocate and free classes, using the constructor and destructor for a class is generally safer coding practice.

Manipulating Strings in a List (see page 2139)

Loading and Saving String Lists (see page 2138)

Associating Objects with a String List (see page 2135)

3.2.4.10.56 Deleting a String from a List

To delete a string from a string list, call the list's *Delete* method, passing the index of the string you want to delete. If you don't know the index of the string you want to delete, use the *IndexOf* method to locate it. To delete all the strings in a string list, use the *Clear* method.

The following example uses *IndexOf* and *Delete* to find and delete a string:

```
with ListBox1.Items do
  begin
    FoundIndex := IndexOf('bureaucracy');
    if FoundIndex > -1 then
      Delete(FoundIndex);
  end;
int BIndex = ListBox1->Items->IndexOf("bureaucracy");
if (BIndex > -1)
  ListBox1->Items->Delete(BIndex);
```

See Also

Manipulating Strings in a List (see page 2139)

3.2.4.10.57 Locating Items in a String List

To locate a string in a string list, use the *IndexOf* method. *IndexOf* returns the index of the first string in the list that matches the parameter passed to it, and returns –1 if the parameter string is not found. *IndexOf* finds exact matches only; if you want to match partial strings, you must iterate through the string list yourself.

For example, you could use *IndexOf* to determine whether a given file name is found among the Items of a list box:

```
if FileListBox1.Items.IndexOf('TargetFileName') > -1 ...
if (FileListBox1->Items->IndexOf("TargetFileName") > -1) ...
```

See Also

Manipulating Strings in a List (see page 2139)

3.2.4.10.58 Iterating Through Strings in a List

To iterate through the strings in a list, use a **for** loop that runs from zero to *Count* –1.

The following example converts each string in a list box to uppercase characters.

```
procedure TForm1.Button1Click(Sender: TObject);var  Index: Integer;
begin
  for Index := 0 to ListBox1.Items.Count - 1 do     ListBox1.Items[Index] :=
UpperCase(ListBox1.Items[Index]);
end;
void __fastcall TForm1::Button1Click(TObject *Sender)
{
  for (int i = 0; i < ListBox1->Items->Count; i++)
    ListBox1->Items->Strings[i] = UpperCase(ListBox1->Items->Strings[i]);
}
```

See Also

Manipulating Strings in a List (see page 2139)

3.2.4.10.59 Loading and Saving String Lists

String-list objects provide *SaveToFile* and *LoadFromFile* methods that let you store a string list in a text file and load a text file into a string list. Each line in the text file corresponds to a string in the list. Using these methods, you could, for example, create a simple text editor by loading a file into a memo component, or save lists of items for combo boxes.

The following example loads a copy of the MyFile.ini file into a memo field and makes a backup copy called MyFile.bak.

```
procedure EditWinIni;
var  FileName: string;{ storage for file name }
```

```
begin  FileName := 'c:\Program Files\MyProgram\MyFile.ini'{ set the file name }

  with Form1.Memo1.Lines do   begin
    LoadFromFile(FileName);{ load from file }
    SaveToFile(ChangeFileExt(FileName, '.bak'));{ save into backup file }
  end;
end;
void __fastcall EditWinIni()
{
  AnsiString FileName = "C:\\Program Files\\MyFile.ini";
  Form1->Memo1->Lines->LoadFromFile(FileName);      // load from file
```

Associating Objects with a String List (see page 2135)

3.2.4.10.60 Manipulating Strings in a List

Operations commonly performed on string lists include:

- Counting the strings in a list (see page 2135)
- Accessing a particular string (see page 2134)
- Finding the position of a string in the list (see page 2138)
- Iterating through strings in a list (see page 2138)
- Adding a string to a list (see page 2134)
- Moving a string within a list
- Deleting a string from a list (see page 2137)
- Copying a complete string list (see page 2135)

See Also

Loading and Saving String Lists (see page 2138)

Creating a New String List (see page 2135)

Working with String Lists (see page 2140)

Associating Objects with a String List (see page 2135)

3.2.4.10.61 Working with Lists

The VCL/RTL includes many classes that represents lists or collections of items. They vary depending on the types of items they contain, what operations they support, and whether they are persistent.

The following table lists various list classes, and indicates the types of items they contain:

Object	Maintains
TList	A list of pointers
TThreadList	A thread-safe list of pointers
TBucketList	A hashed list of pointers

TObjectBucketList	A hashed list of object instances
TObjectList	A memory-managed list of object instances
TComponentList	A memory-managed list of components (that is, instances of classes descended from *TComponent*)
TClassList	A list of class references
TInterfaceList	A list of interface pointers.
TQueue	A first-in first-out list of pointers
TStack	A last-in first-out list of pointers
TObjectQueue	A first-in first-out list of objects
TObjectStack	A last-in first-out list of objects
TCollection	Base class for many specialized classes of typed items.
TStringList	A list of strings
THashedStringList	A list of strings with the form Name=Value, hashed for performance.

Working with String Lists (see page 2140)

Common List Operations (see page 2091)

Persistent Lists (see page 2105)

Working with Strings (see page 2142)

3.2.4.10.62 Working with String Lists

One of the most commonly used types of list is a list of character strings. Examples include items in a combo box, lines in a memo, names of fonts, and names of rows and columns in a string grid. The VCL/RTL provides a common interface to any list of strings through an object called *TStrings* and its descendants such as *TStringList* and *THashedStringList*. *TStringList* implements the abstract properties and methods introduced by *TStrings*, and introduces properties, events, and methods to

- Sort the strings in the list.
- Prohibit duplicate strings in sorted lists.
- Respond to changes in the contents of the list.

In addition to providing functionality for maintaining string lists, these objects allow easy interoperability; for example, you can edit the lines of a memo (which are a *TStrings* descendant) and then use these lines as items in a combo box (also a *TStrings* descendant).

A string-list property appears in the **Object Inspector** with *TStrings* in the Value column. Double-click *TStrings* to open the String List editor, where you can edit, add, or delete lines.

You can also work with string-list objects at runtime to perform such tasks as

- Loading and saving string lists (see page 2138)
- Creating a new string list (see page 2135)
- Manipulating strings in a list (see page 2139)
- Associating objects with a string list (see page 2135)

See Also

Working with Lists (see page 2139)

Loading and Saving String Lists (see page 2138)

3.2.4.10.63 Wide Character Routines

Wide strings contain two bytes per element and are used in a variety of situations. You may also choose to use wide strings because they simplify some of the string-handling issues in applications that have multiple target locales. Using a wide character encoding scheme has the advantage that you can make many of the usual assumptions about strings that do not work for MBCS systems, which are single byte strings. For wide strings, there is a direct relationship between the number of bytes in the string and the number of elements in the string. In a MBCS string, you have to be concerned about cutting characters in half or mistaking the second part of a character for the start of a different character. There is a similar issue for a wide string. Although elements are all two bytes, characters not in the Basic Multilingual Plane (BMP) require two elements.

Two types represent wide strings: `UnicodeString` and `WideString`. The `WideString` format is essentially the same as a Windows `BSTR`. `WideString` is appropriate for use in COM applications. `WideString` is not reference counted, so `UnicodeString` is more flexible and efficient in other types of applications. In addition, more utility functions are available for `UnicodeString` than `WideString`, so `UnicodeString` is generally preferred. This topic deals with `WideString`, not `UnicodeString`.

VCL now uses the `UnicodeString` type; it no longer represents string values as single byte or MBCS strings.

The following functions convert between standard single-byte character strings (or MBCS strings) and Unicode strings:

- StringToWideChar
- WideCharLenToString
- WideCharLenToStrVar
- WideCharToString
- WideCharToStrVar

In addition, the following functions translate between WideStrings and other representations:

- UCS4StringToWideString
- WideStringToUCS4String
- VarToWideStr
- VarToWideStrDef

The following routines work directly with WideStrings:

- WideCompareStr
- WideCompareText
- WideSameStr
- WideSameText
- WideFmtStr
- WideFormat
- WideLowerCase
- WideUpperCase

Finally, some routines include overloads for working with wide strings:

- UniqueString
- Length
- Trim
- TrimLeft

- TrimRight

Unicode in RAD Studio

3.2.4.10.64 Working with Files

The VCL/RTL supports several ways of working with files. In addition to using file streams, there are several runtime library routines for performing file I/O. Both file streams and the global routines for reading from and writing to files are described in Approaches to file I/O (see page 2091).

In addition to input/output operations, you may want to manipulate files on disk. Support for operations on the files themselves rather than their contents is described in Manipulating files (see page 2127).

Note: When writing cross-platform applications, remember that although the Delphi language is not case sensitive, the Linux operating system is. When using objects and routines that work with files, be attentive to the case of file names.

See Also

Using Streams (see page 2099)

Working with ini Files and the System Registry (see page 2099)

3.2.4.10.65 Working with Strings

The runtime library provides many specialized string-handling routines specific to a string type. These are routines for strings (`AnsiString` and `UnicodeString`), wide strings (`WideString`), and null-terminated strings (`PChars`). Routines that deal with null-terminated strings use the null-termination to determine the length of the string. There are no categories of routines listed for *ShortString* types. However, some built-in compiler routines deal with the *ShortString* type. These include, for example, the `Low` and `High` standard functions. For more details about the various string types, see the *Delphi Language Guide*.

The following topics provide an overview of many of the string-handling routines in the runtime library:

- Commonly used long string routines (see page 2118)
- Commonly used routines for null-terminated strings (see page 2121)
- Wide character routines (see page 2141)

3.2.4.11 Working with components

Topics

Name	Description
Adding Custom Components to the Tool Palette (see page 2144)	You can install custom components—written by yourself or third parties—on the **Tool palette** and use them in your applications. To write a custom component, see Overview of component creation (see page 1313). To install an existing component, see Installing component packages (see page 2217).

Associating Menu Events with Event Handlers (see page 2144)	The Menu Designer, along with the *MainMenu* and *PopupMenu* components, make it easy to supply your application with drop-down and pop-up menus. For the menus to work, however, each menu item must respond to the *OnClick* event, which occurs whenever the user chooses the menu item or presses its accelerator or shortcut key. This topic explains how to associate event handlers with menu items. For information about the Menu Designer and related components, see Creating and managing menus (see page 1975).
Calling Methods (see page 2145)	Methods are called just like ordinary procedures and functions. For example, visual controls have a *Repaint* method that refreshes the control's image on the screen. You could call the *Repaint* method in a draw-grid object like this:
Deleting Event Handlers (see page 2145)	When you delete a component from a form using the Form Designer, the Code editor removes the component from the form's type declaration. It does not, however, delete any associated methods from the unit file, since these methods may still be called by other components on the form. You can manually delete a method—such as an event handler—but if you do so, be sure to delete both the method's forward declaration (in the unit's **interface** section) and its implementation (in the **implementation** section). Otherwise you'll get a compiler error when you build your project.
Displaying and Coding Shared Events (see page 2145)	When components share events, you can display their shared events in the **Object Inspector**. First, select the components by holding down the `Shift` key and clicking on them in the Form Designer; then choose the Events tab in the **Object Inspector**. From the Value column in the **Object Inspector**, you can now create a new event handler for, or assign an existing event handler to, any of the shared events.
Associating an Event with an Existing Event Handler (see page 2146)	You can reuse code by writing event handlers that respond to more than one event. For example, many applications provide speed buttons that are equivalent to drop-down menu commands. When a button initiates the same action as a menu command, you can write a single event handler and assign it to both the button's and the menu item's *OnClick* event.
Generating a New Event Handler (see page 2146)	You can generate skeleton event handlers for forms and other components.
Generating a Handler for a Component's Default Event (see page 2147)	Some components have a *default* event, which is the event the component most commonly needs to handle. For example, a button's default event is *OnClick*. To create a default event handler, double-click the component in the Form Designer; this generates a skeleton event-handling procedure and opens the Code editor with the cursor in the body of the procedure, where you can easily add code. Not all components have a default event. Some components, such as *TBevel*, don't respond to any events. Other components respond differently when you double-click them in the Form Designer. For example, many components open... more (see page 2147)
Locating Event Handlers (see page 2147)	If you generated a default event handler for a component by double-clicking it in the Form Designer, you can locate that event handler in the same way. Double-click the component, and the Code editor opens with the cursor at the beginning of the event-handler body.
Setting Properties at Design Time (see page 2147)	When you select a component on a form at design time, the **Object Inspector** displays its published properties and (when appropriate) allows you to edit them. Use the `Tab` key to toggle between the left-hand Property column and the right-hand Value column. When the cursor is in the Property column, you can navigate to any property by typing the first letters of its name. For properties of Boolean or enumerated types, you can choose values from a drop-down list or toggle their settings by double-clicking in Value column. If a plus (+) symbol appears next to a property name, clicking... more (see page 2147)
Setting Component Properties (see page 2148)	You can set component properties at design time or at runtime: • To set published properties at design time, you can use the **Object Inspector** and, in some cases, special property editors. • To set properties at runtime, assign their values in your application source code For information about the properties of each component, see the VCL library in the online Help.
Setting Properties at Runtime (see page 2148)	Any writable property can be set at runtime in your source code. For example, you can dynamically assign a caption to a form:

Using Property Editors (see page 2148)	Some properties, such as *Font*, have special property editors. Such properties appear with ellipsis marks (...) next to their values when the property is selected in the **Object Inspector**. To open the property editor, double-click in the Value column, click the ellipsis mark, or type `Ctrl+Enter` when focus is on the property or its value. With some components, double-clicking the component on the form also opens a property editor. Property editors let you set complex properties from a single dialog box. They provide input validation and often let you preview the results of an assignment.
Using the Sender Parameter (see page 2148)	In an event handler, the *Sender* parameter indicates which component received the event and therefore called the handler. Sometimes it is useful to have several components share an event handler that behaves differently depending on which component calls it. You can do this by using the *Sender* parameter in an **if...then...else** statement. For example, the following code displays the title of the application in the caption of a dialog box only if the *OnClick* event was received by *Button1*.
Working with Events and Event Handlers (see page 2149)	Almost all the code you write is executed, directly or indirectly, in response to events. An event is a special kind of property that represents a runtime occurrence, often a user action. The code that responds directly to an event—called an *event handler*—is a Delphi procedure. The sections that follow show how to: • Generate a new event handler. (see page 2146) • Generate a handler for a component's default event. (see page 2147) • Locate event handlers. (see page 2147) • Associate an event with an existing event handler. (see page 2146) • Associate menu events with event handlers. (see page 2144) • Delete event handlers. (see page 2145)

3.2.4.11.1 Adding Custom Components to the Tool Palette

You can install custom components—written by yourself or third parties—on the **Tool palette** and use them in your applications. To write a custom component, see Overview of component creation (see page 1313). To install an existing component, see Installing component packages (see page 2217).

See Also

Installing Component Packages (see page 2217)

Overview of Component Creation (see page 1313)

3.2.4.11.2 Associating Menu Events with Event Handlers

The Menu Designer, along with the *MainMenu* and *PopupMenu* components, make it easy to supply your application with drop-down and pop-up menus. For the menus to work, however, each menu item must respond to the *OnClick* event, which occurs whenever the user chooses the menu item or presses its accelerator or shortcut key. This topic explains how to associate event handlers with menu items. For information about the Menu Designer and related components, see Creating and managing menus (see page 1975).

To create an event handler for a menu item:

1. Open the Menu Designer by double-clicking on a MainMenu or PopupMenu component.
2. Select a menu item in the Menu Designer. In the **Object Inspector**, make sure that a value is assigned to the item's Name property.
3. From the Menu Designer, double-click the menu item. The Code editor opens with the cursor inside the skeleton event

handler, or the **begin...end** block.

4. At the cursor, type the code that you want to execute when the user selects the menu command.

To associate a menu item with an existing OnClick event handler:

1. Open the Menu Designer by double-clicking a MainMenu or PopupMenu component.
2. Select a menu item in the Menu Designer. In the **Object Inspector**, make sure that a value is assigned to the item's Name property.
3. On the Events page of the **Object Inspector**, click the down arrow in the Value column next to OnClick to open a list of previously written event handlers. (The list includes only event handlers written for OnClick events on this form.) Select from the list by clicking an event handler name.

See Also

Working with Events and Event Handlers (see page 2149)

Deleting Event Handlers (see page 2145)

3.2.4.11.3 Calling Methods

Methods are called just like ordinary procedures and functions. For example, visual controls have a *Repaint* method that refreshes the control's image on the screen. You could call the *Repaint* method in a draw-grid object like this:

```
DrawGrid1.Repaint;
DrawGrid1->Repaint;
```

As with properties, the scope of a method name determines the need for qualifiers. If you want, for example, to repaint a form within an event handler of one of the form's child controls, you don't have to prepend the name of the form to the method call:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
  Repaint;
end;
void __fastcall TForm1::Button1Click(TObject *Sender)
{
Repaint;
}
```

For more information about scope, see Scope and Qualifiers (see page 2070).

3.2.4.11.4 Deleting Event Handlers

When you delete a component from a form using the Form Designer, the Code editor removes the component from the form's type declaration. It does not, however, delete any associated methods from the unit file, since these methods may still be called by other components on the form. You can manually delete a method—such as an event handler—but if you do so, be sure to delete both the method's forward declaration (in the unit's **interface** section) and its implementation (in the **implementation** section). Otherwise you'll get a compiler error when you build your project.

See Also

Working with Events and Event Handlers (see page 2149)

3.2.4.11.5 Displaying and Coding Shared Events

When components share events, you can display their shared events in the **Object Inspector**. First, select the components by holding down the `Shift` key and clicking on them in the Form Designer; then choose the Events tab in the **Object Inspector**. From the Value column in the **Object Inspector**, you can now create a new event handler for, or assign an existing event

handler to, any of the shared events.

See Also

Working with Events and Event Handlers (see page 2149)

Associating an Event with an Existing Event Handler (see page 2146)

Using Action Lists (see page 2007)

3.2.4.11.6 Associating an Event with an Existing Event Handler

You can reuse code by writing event handlers that respond to more than one event. For example, many applications provide speed buttons that are equivalent to drop-down menu commands. When a button initiates the same action as a menu command, you can write a single event handler and assign it to both the button's and the menu item's *OnClick* event.

To associate an event with an existing event handler

1. On the form, select the component whose event you want to handle.
2. On the Events page of the **Object Inspector**, select the event to which you want to attach a handler.
3. Click the down arrow in the Value column next to the event to open a list of previously written event handlers. (The list includes only event handlers written for events of the same name on the same form.) Select from the list by clicking an event-handler name.

The previous procedure is an easy way to reuse event handlers. Action lists (see page 2007) and in the VCL, action bands (see page 2002), however, provide powerful tools for centrally organizing the code that responds to user commands. Action lists can be used in cross-platform applications, whereas action bands cannot.

See Also

Working with Events and Event Handlers (see page 2149)

Using the Sender Parameter (see page 2148)

Displaying and Coding Shared Events (see page 2145)

Associating Menu Events with Event Handlers (see page 2144)

3.2.4.11.7 Generating a New Event Handler

You can generate skeleton event handlers for forms and other components.

To create an event handler:

1. Select a component.
2. Click the Events tab in the **Object Inspector**. The Events page of the **Object Inspector** displays all events defined for the component.
3. Select the event you want, then double-click the Value column or press `Ctrl+Enter`. The Code editor opens with the cursor inside the skeleton event handler, or **begin...end** block.
4. At the cursor, type the code that you want to execute when the event occurs.

See Also

Working with Events and Event Handlers (see page 2149)

Generating a Handler for a Component's Default Event (see page 2147)

3.2.4.11.8 Generating a Handler for a Component's Default Event

Some components have a *default* event, which is the event the component most commonly needs to handle. For example, a button's default event is *OnClick*. To create a default event handler, double-click the component in the Form Designer; this generates a skeleton event-handling procedure and opens the Code editor with the cursor in the body of the procedure, where you can easily add code.

Not all components have a default event. Some components, such as *TBevel*, don't respond to any events. Other components respond differently when you double-click them in the Form Designer. For example, many components open a default property editor or other dialog when they are double-clicked at design time.

See Also

Working with Events and Event Handlers (see page 2149)

Generating a New Event Handler (see page 2146)

Locating Event Handlers (see page 2147)

Associating an Event with an Existing Event Handler (see page 2146)

3.2.4.11.9 Locating Event Handlers

If you generated a default event handler for a component by double-clicking it in the Form Designer, you can locate that event handler in the same way. Double-click the component, and the Code editor opens with the cursor at the beginning of the event-handler body.

To locate an event handler that's not the default:

1. In the form, select the component whose event handler you want to locate.
2. In the **Object Inspector**, click the Events tab.
3. Select the event whose handler you want to view and double-click in the Value column. The Code editor opens with the cursor inside the skeleton event-handler.

See Also

Working with Events and Event Handlers (see page 2149)

Generating a New Event Handler (see page 2146)

3.2.4.11.10 Setting Properties at Design Time

When you select a component on a form at design time, the **Object Inspector** displays its published properties and (when appropriate) allows you to edit them. Use the Tab key to toggle between the left-hand Property column and the right-hand Value column. When the cursor is in the Property column, you can navigate to any property by typing the first letters of its name. For properties of Boolean or enumerated types, you can choose values from a drop-down list or toggle their settings by double-clicking in Value column.

If a plus (+) symbol appears next to a property name, clicking the plus symbol or typing '+' when the property has focus displays a list of subvalues for the property. Similarly, if a minus (-) symbol appears next to the property name, clicking the minus symbol or typing '-' hides the subvalues.

By default, properties in the Legacy category are not shown; to change the display filters, right-click in the **Object Inspector** and choose View.

When more than one component is selected, the **Object Inspector** displays all properties—except *Name*—that are shared by

the selected components. If the value for a shared property differs among the selected components, the **Object Inspector** displays either the default value or the value from the first component selected. When you change a shared property, the change applies to all selected components.

Changing code-related properties, such as the name of an event handler, in the **Object Inspector** automatically changes the corresponding source code. In addition, changes to the source code, such as renaming an event handler method in a form class declaration, is immediately reflected in the **Object Inspector**.

See Also

Using Property Editors (see page 2148)

3.2.4.11.11 Setting Component Properties

You can set component properties at design time or at runtime:

- To set published properties at design time, you can use the **Object Inspector** and, in some cases, special property editors.
- To set properties at runtime, assign their values in your application source code

For information about the properties of each component, see the VCL library in the online Help.

See Also

Setting Properties at Design Time (see page 2147)

Setting Properties at Runtime (see page 2148)

3.2.4.11.12 Setting Properties at Runtime

Any writable property can be set at runtime in your source code. For example, you can dynamically assign a caption to a form:

```
Form1.Caption := MyString;
Form1->Caption = MyString;
```

See Also

Setting Component Properties (see page 2148)

3.2.4.11.13 Using Property Editors

Some properties, such as *Font*, have special property editors. Such properties appear with ellipsis marks (...) next to their values when the property is selected in the **Object Inspector**. To open the property editor, double-click in the Value column, click the ellipsis mark, or type `Ctrl+Enter` when focus is on the property or its value. With some components, double-clicking the component on the form also opens a property editor.

Property editors let you set complex properties from a single dialog box. They provide input validation and often let you preview the results of an assignment.

3.2.4.11.14 Using the Sender Parameter

In an event handler, the *Sender* parameter indicates which component received the event and therefore called the handler. Sometimes it is useful to have several components share an event handler that behaves differently depending on which component calls it. You can do this by using the *Sender* parameter in an **if...then...else** statement. For example, the following code displays the title of the application in the caption of a dialog box only if the *OnClick* event was received by *Button1*.

```
procedure TMainForm.Button1Click(Sender: TObject);
begin
```

```
if Sender = Button1 then
  AboutBox.Caption := 'About ' + Application.Title
else
  AboutBox.Caption := '';
AboutBox.ShowModal;
end;
```

See Also

Working with Events and Event Handlers (see page 2149)

Associating an Event with an Existing Event Handler (see page 2146)

3.2.4.11.15 Working with Events and Event Handlers

Almost all the code you write is executed, directly or indirectly, in response to events. An event is a special kind of property that represents a runtime occurrence, often a user action. The code that responds directly to an event—called an *event handler*—is a Delphi procedure. The sections that follow show how to:

- Generate a new event handler. (see page 2146)
- Generate a handler for a component's default event. (see page 2147)
- Locate event handlers. (see page 2147)
- Associate an event with an existing event handler. (see page 2146)
- Associate menu events with event handlers. (see page 2144)
- Delete event handlers. (see page 2145)

Calling Methods (see page 2145)

Setting Component Properties (see page 2148)

3.2.4.12 Working with controls

Topics

Name	Description
Accepting Dragged Items (see page 2153)	When the user drags something over a control, that control receives an *OnDragOver* event, at which time it must indicate whether it can accept the item if the user drops it there. The drag cursor changes to indicate whether the control can accept the dragged item. To accept items dragged over a control, attach an event handler to the control's *OnDragOver* event. The drag-over event has a parameter called *Accept* that the event handler can set to *True* if it will accept the item. *Accept* changes the cursor type to an accept cursor or not. The drag-over event has other... more (see page 2153)
Adding Graphical Objects to a String List (see page 2154)	Every string list has the ability to hold a list of objects in addition to its list of strings. You can also add graphical objects of varying sizes to a string list. For example, in a file manager application, you may want to add bitmaps indicating the type of drive along with the letter of the drive. To do that, you need to add the bitmap images to the application, then copy those images into the proper places in the string list as described in the following sections. Note that you can also organize graphical objects using an image list... more (see page 2154)

Adding Graphics to Controls (see page 2154)	Several controls let you customize the way the control is rendered. These include list boxes, combo boxes, menus, headers, tab controls, list views, status bars, tree views, and toolbars. Instead of using the standard method of drawing a control or its items, the control's owner (generally, the form) draws them at runtime. The most common use for owner-draw controls is to provide graphics instead of, or in addition to, text for items. For information on using owner-draw to add images to menus, see Adding images to menu items. (see page 1967). All owner-draw controls contain lists of items. Usually, those lists are... more (see page 2154)
Adding Images to a String List (see page 2154)	Once you have graphical images in an application, you can associate them with the strings in a string list. You can either add the objects at the same time as the strings, or associate objects with existing strings. The preferred method is to add objects and strings at the same time, if all the needed data is available. The following example shows how you might want to add images to a string list. This is part of a file manager application where, along with a letter for each valid drive, it adds a bitmap indicating each drive's type. The *OnCreate... more (see page 2154)*
Adding Images to an Application (see page 2155)	An image control is a nonvisual control that contains a graphical image, such as a bitmap. You use image controls to display graphical images on a form. You can also use them to hold hidden images that you'll use in your application. For example,
Adding Scroll Bars at Runtime (see page 2156)	Rich edit and memo components can contain horizontal or vertical scroll bars, or both, as needed. When word wrapping is enabled, the component needs only a vertical scroll bar. If the user turns off word wrapping, the component might also need a horizontal scroll bar, since text is not limited by the right side of the editor.
Adding the Clipboard Object (see page 2156)	Most text-handling applications provide users with a way to move selected text between documents, including documents in different applications. *TClipboard* object encapsulates a clipboard (such as the Windows Clipboard) and includes methods for cutting, copying, and pasting text (and other formats, including graphics). The *Clipboard* object is declared in the *Clipbrd* unit.
Changing the Drag Mouse Pointer (see page 2157)	You can customize the appearance of the mouse pointer during drag operations by setting the source component's *DragCursor* property (VCL only).
Controlling How Child Controls Are Docked (see page 2157)	A docking site automatically accepts child controls when they are released over the docking site. For most controls, the first child is docked to fill the client area, the second splits that into separate regions, and so on. Page controls dock children into new tab sheets (or merge in the tab sheets if the child is another page control). Three events allow docking sites to further constrain how child controls are docked:
Controlling How Child Controls Are Undocked (see page 2158)	A docking site automatically allows child controls to be undocked when they are dragged and have a *DragMode* property of *dmAutomatic*. Docking sites can respond when child controls are dragged off, and even prevent the undocking, in an *OnUnDock* event handler:
Controlling How Child Controls Respond to Drag-and-dock Operations (see page 2158)	Dockable child controls have two events that occur during drag-and-dock operations: *OnStartDock*, analogous to the *OnStartDrag* event of a drag-and-drop operation, allows the dockable child control to create a custom drag object. *OnEndDock*, like *OnEndDrag*, occurs when the dragging terminates.
Customizing Drag and Drop with a Drag Object (see page 2158)	You can use a *TDragObject* descendant to customize an object's drag-and-drop behavior. The standard drag-over and drag-and-drop events indicate the source of the dragged item and the coordinates of the mouse cursor over the accepting control. To get additional state information, derive a custom drag object from *TDragObject* or *TDragObjectEx* (VCL only) and override its virtual methods. Create the custom drag object in the *OnStartDrag* event. Normally, the source parameter of the drag-over and drag-and-drop events is the control that starts the drag operation. If different kinds of control can start an operation involving the same kind of data, the... more (see page 2158)
Cutting, Copying, and Pasting Text (see page 2159)	Applications that use the *Clipbrd* unit can cut, copy, and paste text, graphics, and objects through the clipboard. The edit components that encapsulate the standard text-handling controls all have methods built into them for interacting with the clipboard. To cut, copy, or paste text with the clipboard, call the edit component's *CutToClipboard*, *CopyToClipboard*, and *PasteFromClipboard* methods, respectively. For example, the following code attaches event handlers to the *OnClick* events of the **Edit ▶ Cut**, **Edit ▶ Copy**, and **Edit ▶ Paste** commands, respectively:
Deleting Selected Text (see page 2160)	You can delete the selected text in an edit component without cutting it to the clipboard. To do so, call the *ClearSelection* method. For example, if you have a Delete item on the Edit menu, your code could look like this:

Disabling Menu Items (see page 2160)	It is often useful to disable menu commands without removing them from the menu. For example, in a text editor, if there is no text currently selected, the Cut, Copy, and Delete commands are inapplicable. An appropriate time to enable or disable menu items is when the user selects the menu. To disable a menu item, set its *Enabled* property to *False*. In the following example, an event handler is attached to the *OnClick* event for the Edit item on a child form's menu bar. It sets *Enabled* for the Cut, Copy, and Delete menu items on the Edit... more (see page 2160)
Implementing Drag and Drop in Controls (see page 2160)	Drag-and-drop is often a convenient way for users to manipulate objects. You can let users drag an entire control, or let them drag items from one control—such as a list box or tree view—into another. • Starting a drag operation (see page 2168) • Accepting dragged items (see page 2153) • Dropping items (see page 2162) • Ending a drag operation (see page 2162) • Customizing drag and drop with a drag object (see page 2158) • Changing the drag mouse pointer (see page 2157)
Drawing Owner-draw Items (see page 2161)	When an application needs to draw or redraw an owner-draw control, the operating system generates draw-item events for each visible item in the control. Depending on the control, the item may also receive draw events for the item as a part of the item. To draw each item in an owner-draw control, attach an event handler to the draw-item event for that control. The names of events for owner drawing typically start with one of the following: • *OnDraw*, such as *OnDrawItem* or *OnDrawCell* • *OnCustomDraw*, such as *OnCustomDrawItem* • *OnAdvancedCustomDraw*, such as *OnAdvancedCustomDrawItem* The draw-item event contains parameters identifying... more (see page 2161)
Drawing Owner-drawn Items (see page 2161)	When you indicate that a control is owner-drawn, either by setting a property or supplying a custom draw event handler, the control is no longer drawn on the screen. Instead, the operating system generates events for each visible item in the control. Your application handles the events to draw the items.
Dropping Items (see page 2162)	If a control indicates that it can accept a dragged item, it needs to handle the item should it be dropped. To handle dropped items, attach an event handler to the *OnDragDrop* event of the control accepting the drop. Like the drag-over event, the drag-and-drop event indicates the source of the dragged item and the coordinates of the mouse cursor over the accepting control. The latter parameter allows you to monitor the path an item takes while being dragged; you might, for example, want to use this information to change the color of components if an item is dropped. In... more (see page 2162)
Ending a Drag Operation (see page 2162)	A drag operation ends when the item is either successfully dropped or released over a control that cannot accept it. At this point an end-drag event is sent to the control from which the drag was initiated. To enable a control to respond when items have been dragged from it, attach an event handler to the control's *OnEndDrag* event. The most important parameter in an *OnEndDrag* event is called *Target*, which indicates which control, if any, accepts the drop. If *Target* is **nil**, it means no control accepts the dragged item. The *OnEndDrag* event also includes the coordinates... more (see page 2162)
Handling the OnPopup Event (see page 2163)	You may want to adjust pop-up menu items before displaying the menu, just as you may want to enable or disable items on a regular menu. With a regular menu, you can handle the *OnClick* event for the item at the top of the menu. With a pop-up menu, however, there is no top-level menu bar, so to prepare the pop-up menu commands, you handle the event in the menu component itself. The pop-up menu component provides an event just for this purpose, called *OnPopup*.

Implementing Drag and Dock in Controls (see page 2163)	Descendants of *TWinControl* can act as docking sites and descendants of *TControl* can act as child windows that are docked into docking sites. For example, to provide a docking site at the left edge of a form window, align a panel to the left edge of the form and make the panel a docking site. When dockable controls are dragged to the panel and released, they become child controls of the panel. • Making a windowed control a docking site (see page 2164) • Making a control a dockable child (see page 2164) • Controlling how child controls are docked (see page 2157) • Controlling how child controls are undocked (see page 2158) • Controlling how child (see page 2158)... more (see page 2163)
Making a Control a Dockable Child (see page 2164)	
Making a Windowed Control a Docking Site (see page 2164)	
Providing a Pop-up Menu (see page 2164)	Pop-up, or local, menus are a common ease-of-use feature for any application. They enable users to minimize mouse movement by clicking the right mouse button in the application workspace to access a list of frequently used commands. In a text editor application, for example, you can add a pop-up menu that repeats the Cut, Copy, and Paste editing commands. These pop-up menu items can use the same event handlers as the corresponding items on the Edit menu. You don't need to create accelerator or shortcut keys for pop-up menus because the corresponding regular menu items generally already have shortcuts. A... more (see page 2164)
Selecting All Text (see page 2165)	The *SelectAll* method selects the entire contents of an edit control, such as a rich edit or memo component. This is especially useful when the component's contents exceed the visible area of the component. In most other cases, users select text with either keystrokes or mouse dragging. To select the entire contents of a rich edit or memo control, call the *RichEdit1* control's *SelectAll* method. For example:
Selecting Text (see page 2165)	For text in an edit control, before you can send any text to the clipboard, that text must be selected. Highlighting of selected text is built into the edit components. When the user selects text, it appears highlighted. The table below lists properties commonly used to handle selected text. ***Properties of selected text***
Indicating That a Control Is Owner-drawn (see page 2166)	To customize the drawing of a control, you must supply event handlers that render the control's image when it needs to be painted. Some controls receive these events automatically. For example, list views, tree views, and toolbars all receive events at various stages in the drawing process without your having to set any properties. These events have names such as *OnCustomDraw* or *OnAdvancedCustomDraw*. Other controls, however, require you to set a property before they receive owner-draw events. List boxes, combo boxes, header controls, and status bars have a property called *Style*. *Style* determines whether the control uses the... more (see page 2166)
Setting Text Alignment (see page 2166)	In a rich edit or memo component, text can be left- or right-aligned or centered. To change text alignment, set the edit component's *Alignment* property. Alignment takes effect only if the *WordWrap* property is *True*; if word wrapping is turned off, there is no margin to align to. For example, the following code attaches an *OnClick* event handler to a **Character ▶ Left** menu item, then attaches the same event handler to both a **Character ▶ Right** and **Character ▶ Center** menu item.
Sizing Owner-draw Items (see page 2167)	Before giving your application the chance to draw each item in a variable owner-draw control, the control receives a measure-item event, which is of type *TMeasureItemEvent*. *TMeasureItemEvent* tells the application where the item appears on the control. Delphi determines the size of the item (generally, it is just large enough to display the item's text in the current font). Your application can handle the event and change the rectangle chosen. For example, if you plan to substitute a bitmap for the item's text, change the rectangle to the size of the bitmap. If you want a bitmap and text,... more (see page 2167)

Starting a Drag Operation (see page 2168)	Every control has a property called *DragMode* that determines how drag operations are initiated. If *DragMode* is *dmAutomatic*, dragging begins automatically when the user presses a mouse button with the cursor on the control. Because *dmAutomatic* can interfere with normal mouse activity, you may want to set *DragMode* to *dmManual* (the default) and start the dragging by handling mouse-down events. To start dragging a control manually, call the control's *BeginDrag* method. *BeginDrag* takes a Boolean parameter called *Immediate* and, optionally, an integer parameter called *Threshold*. If you pass *True* for *Immediate*, dragging begins immediately. If you pass... more (see page 2168)
Working with Text in Controls (see page 2168)	The following topics how to use various features of rich edit and memo controls. Some of these features work with edit controls as well. • Setting text alignment (see page 2166) • Adding scrollbars at runtime (see page 2156) • Adding the clipboard object (see page 2156) • Selecting text (see page 2165) • Selecting all text (see page 2165) • Cutting (see page 2159) • Deleting selected text (see page 2160) • Disabling menu items (see page 2160) • Providing a pop-up menu (see page 2164) • Handling the OnPopup event (see page 2163)
Screen Scaling and ChangeScale (see page 2169)	The ChangeScale method is dependent on the BorderStyle property of forms. When BorderStyle is Single, you cannot resize the form manually, and ChangeScale adjusts form size as would be expected. However, if a form's BorderStyle is Sizeable, ChangeScale unexpectedly fails, as if expecting the user to take care of sizing. ChangeScale is sensitive to columns in a DBGrid that have been sized by the developer. ChangeScale typically fails on such columns. This can result in a DBGrid component and Form being adjusted by ChangeScale, but the Columns in the DBGrid not being resized. When implementing either of these methods, it... more (see page 2169)

3.2.4.12.1 Accepting Dragged Items

When the user drags something over a control, that control receives an *OnDragOver* event, at which time it must indicate whether it can accept the item if the user drops it there. The drag cursor changes to indicate whether the control can accept the dragged item. To accept items dragged over a control, attach an event handler to the control's *OnDragOver* event.

The drag-over event has a parameter called *Accept* that the event handler can set to *True* if it will accept the item. *Accept* changes the cursor type to an accept cursor or not.

The drag-over event has other parameters, including the source of the dragging and the current location of the mouse cursor, that the event handler can use to determine whether to accept the drag. In the following VCL example, a directory tree view accepts dragged items only if they come from a file list box.

```
procedure TFMForm.DirectoryOutline1DragOver(Sender, Source: TObject; X,
  Y: Integer; State: TDragState; var Accept: Boolean);
begin
  if Source is TFileListBox then
    Accept := True
  else
    Accept := False;
end;
void __fastcall TForm1::TreeView1DragOver(TObject *Sender, TObject *Source,
  int X, int Y, TDragState State, bool &Accept)
{
  if (Source->InheritsFrom(__classid(TFileListBox)))
```

```
}
```

Implementing Drag and Drop in Controls (see page 2160)

3.2.4.12.2 Adding Graphical Objects to a String List

Every string list has the ability to hold a list of objects in addition to its list of strings. You can also add graphical objects of varying sizes to a string list.

For example, in a file manager application, you may want to add bitmaps indicating the type of drive along with the letter of the drive. To do that, you need to add the bitmap images to the application, then copy those images into the proper places in the string list as described in the following sections.

Note that you can also organize graphical objects using an image list by creating a *TImageList*. However, these images must all be the same size. See Adding images to menu items (see page 1967) for an example of setting up an image list.

See Also

TStringList

TImage

3.2.4.12.3 Adding Graphics to Controls

Several controls let you customize the way the control is rendered. These include list boxes, combo boxes, menus, headers, tab controls, list views, status bars, tree views, and toolbars. Instead of using the standard method of drawing a control or its items, the control's owner (generally, the form) draws them at runtime. The most common use for owner-draw controls is to provide graphics instead of, or in addition to, text for items. For information on using owner-draw to add images to menus, see Adding images to menu items. (see page 1967).

All owner-draw controls contain lists of items. Usually, those lists are lists of strings that are displayed as text, or lists of objects that contain strings that are displayed as text. You can associate an object with each item in the list to make it easy to use that object when drawing items.

To create an owner-draw control:

1. Indicating that a control is owner-drawn. (see page 2166)
2. Adding graphical objects to a string list. (see page 2154)
3. Drawing owner-drawn items. (see page 2161)

See Also

Adding Images to Menu Items (see page 1967)

3.2.4.12.4 Adding Images to a String List

Once you have graphical images in an application, you can associate them with the strings in a string list. You can either add the objects at the same time as the strings, or associate objects with existing strings. The preferred method is to add objects and strings at the same time, if all the needed data is available.

The following example shows how you might want to add images to a string list. This is part of a file manager application where, along with a letter for each valid drive, it adds a bitmap indicating each drive's type. The *OnCreate* event handler looks like this:

```
procedure TFMForm.FormCreate(Sender: TObject);
```

```
var
  Drive: Char;
  AddedIndex: Integer;
begin
  for Drive := 'A' to 'Z' do  { iterate through all possible drives }
  begin
    case GetDriveType(Drive + ':/') of  { positive values mean valid drives }
     DRIVE_REMOVABLE:  { add a tab }
       AddedIndex := DriveTabSet.Tabs.AddObject(Drive, Floppy.Picture.Graphic);
     DRIVE_FIXED:  { add a tab }
       AddedIndex := DriveTabSet.Tabs.AddObject(Drive, Fixed.Picture.Graphic);
     DRIVE_REMOTE:  { add a tab }
       AddedIndex := DriveTabSet.Tabs.AddObject(Drive, Network.Picture.Graphic);
    end;
    if UpCase(Drive) = UpCase(DirectoryOutline.Drive) then  { current drive? }
     DriveTabSet.TabIndex := AddedIndex;  { then make that current tab }
  end;
end;
void __fastcall TFMForm::FormCreate(TObject *Sender)
{
  int AddedIndex;
  char DriveName[4] = "A:\\";
  for (char Drive = "A"; Drive <= "Z"; Drive++) // try all possible drives
  {
    DriveName[0] = Drive;
    switch (GetDriveType(DriveName))
    {
      case DRIVE_REMOVABLE:
        DriveName[1] = "\0"; // temporarily make drive letter into string
        AddedIndex = DriveList->Items->AddObject(DriveName,
           Floppy->Picture->Graphic);
        DriveName[1] = ":" // replace the colon
        break;
      case DRIVE_FIXED:
        DriveName[1] = "\0"; // temporarily make drive letter into string
        AddedIndex = DriveList->Items->AddObject(DriveName,
           Fixed->Picture->Graphic);
        DriveName[1] = ":" // replace the colon
        break;
      case DRIVE_REMOTE:
        DriveName[1] = "\0"; // temporarily make drive letter into string
        AddedIndex = DriveList->Items->AddObject(DriveName,
           Network->Picture->Graphic);
        DriveName[1] = ":" // replace the colon
        break;
    }
    if ((reinterpret_cast<int>(Drive - "A")) == getdisk()) // current drive?
      DriveList->ItemIndex = AddedIndex; // then make that the current list item
  }
}
```

TStringList

3.2.4.12.5 Adding Images to an Application

An image control is a nonvisual control that contains a graphical image, such as a bitmap. You use image controls to display graphical images on a form. You can also use them to hold hidden images that you'll use in your application. For example,

To store bitmaps for owner-draw controls in hidden image controls:

1. Add image controls to the main form.
2. Set their *Name* properties.

3. Set the Visible property for each image control to *False*.
4. Set the *Picture* property of each image to the desired bitmap using the Picture editor from the **Object Inspector**.

The image controls are invisible when you run the application. The image is stored with the form so it doesn't have to be loaded from a file at runtime.

See Also

TImage

3.2.4.12.6 Adding Scroll Bars at Runtime

Rich edit and memo components can contain horizontal or vertical scroll bars, or both, as needed. When word wrapping is enabled, the component needs only a vertical scroll bar. If the user turns off word wrapping, the component might also need a horizontal scroll bar, since text is not limited by the right side of the editor.

To add scroll bars at runtime:

1. Determine whether the text might exceed the right margin. In most cases, this means checking whether word wrapping is enabled. You might also check whether any text lines actually exceed the width of the control.
2. Set the rich edit or memo component's *ScrollBars* property to include or exclude scroll bars.

The following example attaches an *OnClick* event handler to a **Character ▸ WordWrap** menu item.

```
procedure TForm.WordWrap1Click(Sender: TObject);
begin
  with Editor do
  begin
    WordWrap := not WordWrap;  { toggle word wrapping }
    if WordWrap then
      ScrollBars := ssVertical  { wrapped requires only vertical }
    else
      ScrollBars := ssBoth;  { unwrapped might need both }
      WordWrap1.Checked := WordWrap;  { check menu item to match property }
  end;
end;
void __fastcall TForm::WordWrap1Click(TObject *Sender)
{
  Editor->WordWrap = !(Editor->WordWrap);   // toggle word wrapping
  if (Editor->WordWrap)
    Editor->ScrollBars = ssVertical;        // wrapped requires only vertical
  else
    Editor->ScrollBars = ssBoth;            // unwrapped can need both
  WordWrap1->Checked = Editor->WordWrap;    // check menu item to match property
}
```

The rich edit and memo components handle their scroll bars in a slightly different way. The rich edit component can hide its scroll bars if the text fits inside the bounds of the component. The memo always shows scroll bars if they are enabled.

TMemo

TRichEdit

3.2.4.12.7 Adding the Clipboard Object

Most text-handling applications provide users with a way to move selected text between documents, including documents in different applications. *TClipboard* object encapsulates a clipboard (such as the Windows Clipboard) and includes methods for cutting, copying, and pasting text (and other formats, including graphics). The *Clipboard* object is declared in the *Clipbrd* unit.

To add the Clipboard object to an application:

1. Select the unit that will use the clipboard.
2. Search for the **implementation** reserved word.
3. Add *Clipbrd* to the **uses** clause below **implementation**.

- If there is already a **uses** clause in the **implementation** part, add *Clipbrd* to the end of it.
- If there is not already a **uses** clause, add one that says

```
    uses Clipbrd;
#include <vcl\Clipbrd.hpp>
```

For example, in an application with a child window, the uses clause in the unit's implementation part might look like this:

```
uses
  MDIFrame, Clipbrd;
```

TWinControl

3.2.4.12.9 Controlling How Child Controls Are Docked

A docking site automatically accepts child controls when they are released over the docking site. For most controls, the first child is docked to fill the client area, the second splits that into separate regions, and so on. Page controls dock children into new tab sheets (or merge in the tab sheets if the child is another page control).

Three events allow docking sites to further constrain how child controls are docked:

```
property OnGetSiteInfo: TGetSiteInfoEvent;
TGetSiteInfoEvent = procedure(Sender: TObject; DockClient: TControl; var   InfluenceRect:
TRect; var CanDock: Boolean) of object;
__property TGetSiteInfoEvent OnGetSiteInfo = {read=FOnGetSiteInfo, write=FOnGetSiteInfo};
typedef void __fastcall (__closure *TGetSiteInfoEvent)(System::TObject* Sender, TControl*
DockClient, Windows::TRect &InfluenceRect, const Windows::TPoint &MousePos, bool &CanDock);
```

OnGetSiteInfo occurs on the docking site when the user drags a dockable child over the control. It allows the site to indicate whether it will accept the control specified by the *DockClient* parameter as a child, and if so, where the child must be to be considered for docking. When *OnGetSiteInfo* occurs, *InfluenceRect* is initialized to the screen coordinates of the docking site, and *CanDock* is initialized to *True*. A more limited docking region can be created by changing *InfluenceRect* and the child can be rejected by setting *CanDock* to *False*.

```
property OnDockOver: TDockOverEvent;
TDockOverEvent = procedure(Sender: TObject; Source: TDragDockObject; X, Y:  Integer; State:
TDragState; var Accept: Boolean) of object;
__property TDockOverEvent OnDockOver = {read=FOnDockOver, write=FOnDockOver};
typedef void __fastcall (__closure *TDockOverEvent)(System::TObject* Sender, TDragDockObject*
Source, int X, int Y, TDragState State, bool &Accept);
```

OnDockOver occurs on the docking site when the user drags a dockable child over the control. It is analogous to the *OnDragOver* event in a drag-and-drop operation. Use it to signal that the child can be released for docking, by setting the *Accept*

parameter. If the dockable control is rejected by the *OnGetSiteInfo* event handler (perhaps because it is the wrong type of control), *OnDockOver* does not occur.

```
property OnDockDrop: TDockDropEvent;
TDockDropEvent = procedure(Sender: TObject; Source: TDragDockObject; X, Y:  Integer) of object;
__property TDockDropEvent OnDockDrop = {read=FOnDockDrop, write=FOnDockDrop};
typedef void __fastcall (__closure *TDockDropEvent)(System::TObject* Sender, TDragDockObject*
Source, int X, int Y);
```

OnDockDrop occurs on the docking site when the user releases the dockable child over the control. It is analogous to the *OnDragDrop* event in a normal drag-and-drop operation. Use this event to perform any necessary accommodations to accepting the control as a child control. Access to the child control can be obtained using the *Control* property of the *TDockObject* specified by the *Source* parameter.

TControl

3.2.4.12.10 Controlling How Child Controls Are Undocked

A docking site automatically allows child controls to be undocked when they are dragged and have a *DragMode* property of *dmAutomatic*. Docking sites can respond when child controls are dragged off, and even prevent the undocking, in an *OnUnDock* event handler:

```
property OnUnDock: TUnDockEvent;
TUnDockEvent = procedure(Sender: TObject; Client: TControl; var Allow: Boolean)   of object;
__property TUnDockEvent OnUnDock = {read=FOnUnDock, write=FOnUnDock};
typedef void __fastcall (__closure *TUnDockEvent)(System::TObject* Sender, TControl* Client,
TWinControl* NewTarget, bool &Allow);
```

The *Client* parameter indicates the child control that is trying to undock, and the *Allow* parameter lets the docking site (*Sender*) reject the undocking. When implementing an *OnUnDock* event handler, it can be useful to know what other children (if any) are currently docked. This information is available in the read-only *DockClients* property, which is an indexed array of *TControl*. The number of dock clients is given by the read-only *DockClientCount* property.

TControl

3.2.4.12.11 Controlling How Child Controls Respond to Drag-and-dock Operations

Dockable child controls have two events that occur during drag-and-dock operations: *OnStartDock*, analogous to the *OnStartDrag* event of a drag-and-drop operation, allows the dockable child control to create a custom drag object. *OnEndDock*, like *OnEndDrag*, occurs when the dragging terminates.

3.2.4.12.12 Customizing Drag and Drop with a Drag Object

You can use a *TDragObject* descendant to customize an object's drag-and-drop behavior. The standard drag-over and

drag-and-drop events indicate the source of the dragged item and the coordinates of the mouse cursor over the accepting control. To get additional state information, derive a custom drag object from *TDragObject* or *TDragObjectEx* (VCL only) and override its virtual methods. Create the custom drag object in the *OnStartDrag* event.

Normally, the source parameter of the drag-over and drag-and-drop events is the control that starts the drag operation. If different kinds of control can start an operation involving the same kind of data, the source needs to support each kind of control. When you use a descendant of *TDragObject*, however, the source is the drag object itself; if each control creates the same kind of drag object in its *OnStartDrag* event, the target needs to handle only one kind of object. The drag-over and drag-and-drop events can tell if the source is a drag object, as opposed to the control, by calling the *IsDragObject* function.

TDragObjectEx descendants (VCL only) are freed automatically whereas descendants of *TDragObject* are not. If you have *TDragObject* descendants that you are not explicitly freeing, you can change them so they descend from *TDragObjectEx* instead to prevent memory loss.

Drag objects let you drag items between a form implemented in the application's main executable file and a form implemented using a DLL, or between forms that are implemented using different DLLs.

IsDragObjectfunction

3.2.4.12.13 Cutting, Copying, and Pasting Text

Applications that use the *Clipbrd* unit can cut, copy, and paste text, graphics, and objects through the clipboard. The edit components that encapsulate the standard text-handling controls all have methods built into them for interacting with the clipboard.

To cut, copy, or paste text with the clipboard, call the edit component's *CutToClipboard*, *CopyToClipboard*, and *PasteFromClipboard* methods, respectively.

For example, the following code attaches event handlers to the *OnClick* events of the **Edit ▸ Cut**, **Edit ▸ Copy**, and **Edit ▸ Paste** commands, respectively:

```
procedure TEditForm.CutToClipboard(Sender: TObject);
begin
  Editor.CutToClipboard;
end;
procedure TEditForm.CopyToClipboard(Sender: TObject);
begin
  Editor.CopyToClipboard;
end;
procedure TEditForm.PasteFromClipboard(Sender: TObject);
begin
  Editor.PasteFromClipboard;
end;
void __fastcall TMainForm::EditCutClick(TObject* Sender)
{    RichEdit1->CutToClipboard();
}
void __fastcall TMainForm::EditCopyClick(TObject* Sender)
{    RichEdit1->CopyToClipboard();
}
void __fastcall TMainForm::EditPasteClick(TObject* Sender)
{    RichEdit1->PasteFromClipboard();
}
```

Using the Clipboard with Graphics (see page 2206)

TClipboard

3.2.4.12.14 Deleting Selected Text

You can delete the selected text in an edit component without cutting it to the clipboard. To do so, call the *ClearSelection* method. For example, if you have a Delete item on the Edit menu, your code could look like this:

```
procedure TEditForm.Delete(Sender: TObject);
begin
  RichEdit1.ClearSelection;
end;
void __fastcall TMainForm::EditDeleteClick(TObject *Sender)
{
  RichEdit1->ClearSelection();
}
```

3.2.4.12.15 Disabling Menu Items

It is often useful to disable menu commands without removing them from the menu. For example, in a text editor, if there is no text currently selected, the Cut, Copy, and Delete commands are inapplicable. An appropriate time to enable or disable menu items is when the user selects the menu. To disable a menu item, set its *Enabled* property to *False*.

In the following example, an event handler is attached to the *OnClick* event for the Edit item on a child form's menu bar. It sets *Enabled* for the Cut, Copy, and Delete menu items on the Edit menu based on whether *RichEdit1* has selected text. The Paste command is enabled or disabled based on whether any text exists on the clipboard.

```
procedure TEditForm.Edit1Click(Sender: TObject);
var
  HasSelection: Boolean;  { declare a temporary variable }
begin
  Paste1.Enabled := Clipboard.HasFormat(CF_TEXT);  {enable or disable the
Paste                                                menu item}
  HasSelection := Editor.SelLength > 0;  { True if text is selected }
  Cut1.Enabled := HasSelection;  { enable menu items if HasSelection is True }
  Copy1.Enabled := HasSelection;
  Delete1.Enabled := HasSelection;
end;
void __fastcall TMainForm::EditEditClick(TObject *Sender)
{
  // enable or disable the Paste menu item
  Paste1->Enabled = Clipboard()->HasFormat(CF_TEXT);
  bool HasSelection = (RichEdit1->SelLength > 0);  // true if text is selected
  Cut1->Enabled = HasSelection;  // enable menu items if HasSelection is true
  Copy1->Enabled = HasSelection;
  Delete1->Enabled = HasSelection;
}
```

The *HasFormat* method of the clipboard returns a Boolean value based on whether the clipboard contains objects, text, or images of a particular format. By calling *HasFormat* with the parameter *CF_TEXT*, you can determine whether the clipboard contains any text, and enable or disable the Paste item as appropriate.

3.2.4.12.16 Implementing Drag and Drop in Controls

Drag-and-drop is often a convenient way for users to manipulate objects. You can let users drag an entire control, or let them drag items from one control—such as a list box or tree view—into another.

- Starting a drag operation (see page 2168)
- Accepting dragged items (see page 2153)
- Dropping items (see page 2162)
- Ending a drag operation (see page 2162)
- Customizing drag and drop with a drag object (see page 2158)
- Changing the drag mouse pointer (see page 2157)

3.2.4.12.17 Drawing Owner-draw Items

When an application needs to draw or redraw an owner-draw control, the operating system generates draw-item events for each visible item in the control. Depending on the control, the item may also receive draw events for the item as a part of the item.

To draw each item in an owner-draw control, attach an event handler to the draw-item event for that control.

The names of events for owner drawing typically start with one of the following:

- *OnDraw*, such as *OnDrawItem* or *OnDrawCell*
- *OnCustomDraw*, such as *OnCustomDrawItem*
- *OnAdvancedCustomDraw*, such as *OnAdvancedCustomDrawItem*

The draw-item event contains parameters identifying the item to draw, the rectangle in which to draw, and usually some information about the state of the item (such as whether the item has focus). The application handles each event by rendering the appropriate item in the given rectangle.

For example, the following code shows how to draw items in a list box that has bitmaps associated with each string. It attaches this handler to the *OnDrawItem* event for the list box:

```
procedure TFMForm.DriveTabSetDrawTab(Sender: TObject; TabCanvas: TCanvas;
  R: TRect; Index: Integer; Selected: Boolean);
var
  Bitmap: TBitmap;
begin
  Bitmap := TBitmap(DriveTabSet.Tabs.Objects[Index]);
  with TabCanvas do
  begin
     Draw(R.Left, R.Top + 4, Bitmap);  { draw bitmap }
     TextOut(R.Left + 2 + Bitmap.Width,  { position text }
     R.Top + 2, DriveTabSet.Tabs[Index]);  { and draw it to the right of the bitmap }
  end;
end;
void __fastcall TForm1::ListBox1DrawItem(TWinControl *Control, int Index,
  TRect &Rect, TOwnerDrawState State)
  TBitmap *Bitmap = (TBitmap *)ListBox1->Items->Objects[Index];
  ListBox1->Canvas->Draw(R.Left, R.Top + 2, Bitmap); // draw the bitmap
  ListBox1->Canvas->TextOut(R.Left + Bitmap->Width + 2, R.Top + 2,
    ListBox1->Items->Strings[Index]);        // and write the text to its right
}
```

3.2.4.12.18 Drawing Owner-drawn Items

When you indicate that a control is owner-drawn, either by setting a property or supplying a custom draw event handler, the control is no longer drawn on the screen. Instead, the operating system generates events for each visible item in the control. Your application handles the events to draw the items.

To draw the items in an owner-draw control, do the following for each visible item in the control. Use a single event handler for all items.

1. Size the item, if needed. Items of the same size (for example, with a list box style of *lsOwnerDrawFixed*), do not require sizing.
2. Draw the item.

3.2.4.12.19 Dropping Items

If a control indicates that it can accept a dragged item, it needs to handle the item should it be dropped. To handle dropped items, attach an event handler to the *OnDragDrop* event of the control accepting the drop. Like the drag-over event, the drag-and-drop event indicates the source of the dragged item and the coordinates of the mouse cursor over the accepting control. The latter parameter allows you to monitor the path an item takes while being dragged; you might, for example, want to use this information to change the color of components if an item is dropped.

In the following VCL example, a directory tree view, accepting items dragged from a file list box, responds by moving files to the directory on which they are dropped.

```
procedure TFMForm.DirectoryOutline1DragDrop(Sender, Source: TObject; X,
  Y: Integer);
begin
  if Source is TFileListBox then
    with DirectoryOutline1 do
      ConfirmChange('Move', FileListBox1.FileName, Items[GetItem(X, Y)].FullPath);
end;
void __fastcall TForm1::TreeView1DragDrop(TObject *Sender, TObject *Source,
  if (Source->InheritsFrom(__classid(TFileListBox)))
  {
    TTreeNode *pNode = TreeView1->GetNodeAt(X,Y); // pNode is drop target
    AnsiString NewFile = pNode->Text + AnsiString("//") +
      ExtractFileName(FileListBox1->FileName); // build file name for drop target
    MoveFileEx(FileListBox1->FileName.c_str(), NewFile.c_str(),
      MOVEFILE_REPLACE_EXISTING | MOVEFILE_COPY_ALLOWED); // move the file
  }
}
```

Implementing Drag and Drop in Controls (see page 2160)

3.2.4.12.20 Ending a Drag Operation

A drag operation ends when the item is either successfully dropped or released over a control that cannot accept it. At this point an end-drag event is sent to the control from which the drag was initiated. To enable a control to respond when items have been dragged from it, attach an event handler to the control's *OnEndDrag* event.

The most important parameter in an *OnEndDrag* event is called *Target*, which indicates which control, if any, accepts the drop. If *Target* is **nil**, it means no control accepts the dragged item. The *OnEndDrag* event also includes the coordinates on the receiving control.

In the following VCL example, a file list box handles an end-drag event by refreshing its file list.

```
procedure TFMForm.FileListBox1EndDrag(Sender, Target: TObject; X, Y: Integer);
begin
  if Target <> nil then FileListBox1.Update;
end;
void __fastcall TFMForm::FileListBox1EndDrag(TObject *Sender, TObject *Target,   int X, int Y)
  if (Target)
    FileListBox1->Update();
```

```
};
```

3.2.4.12.21 Handling the OnPopup Event

You may want to adjust pop-up menu items before displaying the menu, just as you may want to enable or disable items on a regular menu. With a regular menu, you can handle the *OnClick* event for the item at the top of the menu.

With a pop-up menu, however, there is no top-level menu bar, so to prepare the pop-up menu commands, you handle the event in the menu component itself. The pop-up menu component provides an event just for this purpose, called *OnPopup*.

To adjust menu items on a pop-up menu before displaying them:

1. Select the pop-up menu component.
2. Attach an event handler to its *OnPopup* event.
3. Write code in the event handler to enable, disable, hide, or show menu items.

In the following code, the *Edit1Click* event handler described previously in Disabling menu items (see page 2160) is attached to the pop-up menu component's OnPopup event. A line of code is added to *Edit1Click* for each item in the pop-up menu.

```
procedure TEditForm.Edit1Click(Sender: TObject);
var
  HasSelection: Boolean;
begin
  Paste1.Enabled := Clipboard.HasFormat(CF_TEXT);
  Paste2.Enabled := Paste1.Enabled;{Add this line}
  HasSelection := Editor.SelLength <> 0;
  Cut1.Enabled := HasSelection;
  Cut2.Enabled := HasSelection;{Add this line}
  Copy1.Enabled := HasSelection;
  Copy2.Enabled := HasSelection;{Add this line}
  Delete1.Enabled := HasSelection;
end;
void __fastcall TMainForm::EditEditClick(TObject *Sender)
{
  // enable or disable the Paste menu item
  Paste1->Enabled = Clipboard()->HasFormat(CF_TEXT);
  Paste2->Enabled = Paste1->Enabled;            // add this line
  bool HasSelection = (RichEdit1->SelLength > 0);  // true if text is selected
  Cut1->Enabled = HasSelection;    // enable menu items if HasSelection is true
  Cut2->Enabled = HasSelection;    // add this line
  Copy1->Enabled = HasSelection;
  Copy2->Enabled = HasSelection;   // add this line
  Delete1->Enabled = HasSelection;
}
```

3.2.4.12.22 Implementing Drag and Dock in Controls

Descendants of *TWinControl* can act as docking sites and descendants of *TControl* can act as child windows that are docked into docking sites. For example, to provide a docking site at the left edge of a form window, align a panel to the left edge of the form and make the panel a docking site. When dockable controls are dragged to the panel and released, they become child controls of the panel.

- Making a windowed control a docking site (see page 2164)
- Making a control a dockable child (see page 2164)

- Controlling how child controls are docked (see page 2157)
- Controlling how child controls are undocked (see page 2158)
- Controlling how child controls respond to drag-and-dock operations (see page 2158)

3.2.4.12.23 Making a Control a Dockable Child

To make a control a dockable child:

1. Set its *DragKind* property to *dkDock*. When *DragKind* is *dkDock*, dragging the control moves the control to a new docking site or undocks the control so that it becomes a floating window. When *DragKind* is *dkDrag* (the default), dragging the control starts a drag-and-drop operation which must be implemented using the *OnDragOver*, *OnEndDrag*, and *OnDragDrop* events.
2. Set its *DragMode* to *dmAutomatic*. When *DragMode* is *dmAutomatic*, dragging (for drag-and-drop or docking, depending on *DragKind*) is initiated automatically when the user starts dragging the control with the mouse. When *DragMode* is *dmManual*, you can still begin a drag-and-dock (or drag-and-drop) operation by calling the *BeginDrag* method.
3. Set its *FloatingDockSiteClass* property to indicate the *TWinControl* descendant that should host the control when it is undocked and left as a floating window. When the control is released and not over a docking site, a windowed control of this class is created dynamically, and becomes the parent of the dockable child. If the dockable child control is a descendant of *TWinControl*, it is not necessary to create a separate floating dock site to host the control, although you may want to specify a form in order to get a border and title bar. To omit a dynamic container window, set *FloatingDockSiteClass* to the same class as the control, and it will become a floating window with no parent.

TWinControl

TControl

3.2.4.12.24 Making a Windowed Control a Docking Site

To make a windowed control a docking site:

1. Set the *DockSite* property to *True*.
2. If the dock site object should not appear except when it contains a docked client, set its *AutoSize* property to *True*. When *AutoSize* is *True*, the dock site is sized to 0 until it accepts a child control for docking. Then it resizes to fit around the child control.

TControl

3.2.4.12.25 Providing a Pop-up Menu

Pop-up, or local, menus are a common ease-of-use feature for any application. They enable users to minimize mouse movement by clicking the right mouse button in the application workspace to access a list of frequently used commands.

In a text editor application, for example, you can add a pop-up menu that repeats the Cut, Copy, and Paste editing commands. These pop-up menu items can use the same event handlers as the corresponding items on the Edit menu. You don't need to create accelerator or shortcut keys for pop-up menus because the corresponding regular menu items generally already have shortcuts.

A form's *PopupMenu* property specifies what pop-up menu to display when a user right-clicks any item on the form. Individual controls also have *PopupMenu* properties that can override the form's property, allowing customized menus for particular controls.

To add a pop-up menu to a form:

1. Place a pop-up menu component on the form.
2. Use the Menu Designer to define the items for the pop-up menu.
3. Set the *PopupMenu* property of the form or control that displays the menu to the name of the pop-up menu component.
4. Attach handlers to the *OnClick* events of the pop-up menu items.

See Also

TPopupMenu

Handling the OnPopup Event (see page 2163)

3.2.4.12.26 Selecting All Text

The *SelectAll* method selects the entire contents of an edit control, such as a rich edit or memo component. This is especially useful when the component's contents exceed the visible area of the component. In most other cases, users select text with either keystrokes or mouse dragging.

To select the entire contents of a rich edit or memo control, call the *RichEdit1* control's *SelectAll* method.

For example:

```
procedure TMainForm.SelectAll(Sender: TObject);
begin
  RichEdit1.SelectAll;  { select all text in RichEdit }
end;
void __fastcall TMainForm::SelectAll(TObject *Sender)
{
  RichEdit1->SelectAll();     // select all text in RichEdit
}
```

3.2.4.12.27 Selecting Text

For text in an edit control, before you can send any text to the clipboard, that text must be selected. Highlighting of selected text is built into the edit components. When the user selects text, it appears highlighted.

The table below lists properties commonly used to handle selected text.

Properties of selected text

Property	Description
SelText	Contains a string representing the selected text in the component.
SelLength	Contains the length of a selected string.
SelStart	Contains the starting position of a string relative to the beginning of an edit control's text buffer.

For example, the following *OnFind* event handler searches a Memo component for the text specified in the *FindText* property of a find dialog component. If found, the first occurrence of the text in Memo1 is selected.

```
procedure TForm1.FindDialog1Find(Sender: TObject);
var
I, J, PosReturn, SkipChars: Integer;
begin
for I := 0 to Memo1.Lines.Count do
```

```
begin
PosReturn := Pos(FindDialog1.FindText,Memo1.Lines[I]);
if PosReturn <> 0 then {found!}
begin
Skipchars := 0;
for J := 0 to I - 1 do
Skipchars := Skipchars + Length(Memo1.Lines[J]);
SkipChars := SkipChars + (I*2);
SkipChars := SkipChars + PosReturn - 1;
      Memo1.SetFocus;
Memo1.SelStart := SkipChars;
Memo1.SelLength := Length(FindDialog1.FindText);
Break;
end;
end;
end;
```

3.2.4.12.28 Indicating That a Control Is Owner-drawn

To customize the drawing of a control, you must supply event handlers that render the control's image when it needs to be painted. Some controls receive these events automatically. For example, list views, tree views, and toolbars all receive events at various stages in the drawing process without your having to set any properties. These events have names such as *OnCustomDraw* or *OnAdvancedCustomDraw*.

Other controls, however, require you to set a property before they receive owner-draw events. List boxes, combo boxes, header controls, and status bars have a property called *Style*. *Style* determines whether the control uses the default drawing (called the "standard" style) or owner drawing. Grids use a property called *DefaultDrawing* to enable or disable the default drawing. List views and tab controls have a property called *OwnerDraw* that enables or disabled the default drawing.

List boxes and combo boxes have additional owner-draw styles, called fixed and *variable*, as the following table describes. Other controls are always fixed, although the size of the item that contains the text may vary, the size of each item is determined before drawing the control.

Fixed vs. variable owner-draw styles

Owner-draw style	Meaning	Examples
Fixed	Each item is the same height, with that height determined by the ItemHeight property.	*lbOwnerDrawFixed*,*csOwnerDrawFixed*
Variable	Each item might have a different height, determined by the data at runtime.	*lbOwnerDrawVariable*, *csOwnerDrawVariable*

3.2.4.12.29 Setting Text Alignment

In a rich edit or memo component, text can be left- or right-aligned or centered. To change text alignment, set the edit component's *Alignment* property. Alignment takes effect only if the *WordWrap* property is *True*; if word wrapping is turned off, there is no margin to align to.

For example, the following code attaches an *OnClick* event handler to a **Character ▸ Left** menu item, then attaches the same event handler to both a **Character ▸ Right** and **Character ▸ Center** menu item.

```
procedure TForm.AlignClick(Sender: TObject);
begin
  Left1.Checked := False;  { clear all three checks }
```

```
  Right1.Checked := False;
  Center1.Checked := False;
  with Sender as TMenuItem do Checked := True;  { check the item clicked }
  with Editor do  { then set Alignment to match }
    if Left1.Checked then
      Alignment := taLeftJustify
    else if Right1.Checked then
      Alignment := taRightJustify
    else if Center1.Checked then
      Alignment := taCenter;
end;
```

```
switch(reinterpret_cast<int>(RichEdit1->Paragraph->Alignment))
{
  case 0: LeftAlign->Down   = true; break;
  case 1: RightAlign->Down  = true; break;
  case 2: CenterAlign->Down = true; break;
}
```

You can also use the *HMargin* property to adjust the left and right margins in a memo control.

TRichEdit

3.2.4.12.30 Sizing Owner-draw Items

Before giving your application the chance to draw each item in a variable owner-draw control, the control receives a measure-item event, which is of type *TMeasureItemEvent*. *TMeasureItemEvent* tells the application where the item appears on the control.

Delphi determines the size of the item (generally, it is just large enough to display the item's text in the current font). Your application can handle the event and change the rectangle chosen. For example, if you plan to substitute a bitmap for the item's text, change the rectangle to the size of the bitmap. If you want a bitmap and text, adjust the rectangle to be large enough for both.

To change the size of an owner-draw item, attach an event handler to the measure-item event in the owner-draw control. Depending on the control, the name of the event can vary. List boxes and combo boxes use *OnMeasureItem*. Grids have no measure-item event.

The sizing event has two important parameters: the index number of the item and the height of that item. The height is variable: the application can make it either smaller or larger. The positions of subsequent items depend on the size of preceding items.

For example, in a variable owner-draw list box, if the application sets the height of the first item to five pixels, the second item starts at the sixth pixel down from the top, and so on. In list boxes and combo boxes, the only aspect of the item the application can alter is the height of the item. The width of the item is always the width of the control.

Owner-draw grids cannot change the sizes of their cells as they draw. The size of each row and column is set before drawing by the *ColWidths* and *RowHeights* properties.

The following code, attached to the *OnMeasureItem* event of an owner-draw list box, increases the height of each list item to accommodate its associated bitmap.

```
procedure TFMForm.ListBox1MeasureItem(Control: TWinControl; Index: Integer;
  var Height: Integer);  { note that Height is a var parameter}
var
  BitmapHeight: Integer;
begin
  BitmapHeight := TBitmap(ListBox1.Items.Objects[Index]).Height;
  { make sure the item height has enough room, plus two }
  Height := Max(Height, Bitmap Height +2);
```

```
end;
void __fastcall TForm1::ListBox1MeasureItem(TWinControl *Control, int Index,
  int &Height)      // note that Height is passed by reference
{
  int BitmapHeight = (dynamic_cast<TBitmap *>(ListBox1->Items->Objects[Index]))->Height + 2;
  // make sure list item has enough room for bitmap (plus two)
  Height = Max(Height, Bitmap Height +2);
}
```

Note: You must typecast the items from the *Objects* property in the string list. *Objects* is a property of type *TObject* so that it can hold any kind of object. When you retrieve objects from the array, you need to typecast them back to the actual type of the items.

3.2.4.12.31 Starting a Drag Operation

Every control has a property called *DragMode* that determines how drag operations are initiated. If *DragMode* is *dmAutomatic*, dragging begins automatically when the user presses a mouse button with the cursor on the control. Because *dmAutomatic* can interfere with normal mouse activity, you may want to set *DragMode* to *dmManual* (the default) and start the dragging by handling mouse-down events.

To start dragging a control manually, call the control's *BeginDrag* method. *BeginDrag* takes a Boolean parameter called *Immediate* and, optionally, an integer parameter called *Threshold*. If you pass *True* for *Immediate*, dragging begins immediately. If you pass *False*, dragging does not begin until the user moves the mouse the number of pixels specified by *Threshold*. Calling

```
BeginDrag (False);
false, -1
```

allows the control to accept mouse clicks without beginning a drag operation.

You can place other conditions on whether to begin dragging, such as checking which mouse button the user pressed, by testing the parameters of the mouse-down event before calling *BeginDrag*. The following code, for example, handles a mouse-down event in a file list box by initiating a drag operation only if the left mouse button was pressed.

```
procedure TFMForm.FileListBox1MouseDown(Sender: TObject;
  Button: TMouseButton; Shift: TShiftState; X, Y: Integer);
begin
  if Button = mbLeft then  { drag only if left button pressed }
    with Sender as TFileListBox do  { treat Sender as TFileListBox }
      begin
        if ItemAtPos(Point(X, Y), True) >= 0 then  { is there an item here? }
          BeginDrag(False);  { if so, drag it }
    end;
end;
void __fastcall TFMForm::FileListBox1MouseDown(TObject *Sender,
{
  if (Button == mbLeft)
  {
    TFileListBox *pLB = dynamic_cast<TFileListBox *>(Sender); // cast to TFileListBox
    if (pLB && pLB->ItemAtPos(Point(X,Y), true) >= 0) // is there an item here?
      pLB->BeginDrag(false, -1);                      // if so, drag it
  }
}
```

Implementing Drag and Drop in Controls (see page 2160)

3.2.4.12.32 Working with Text in Controls

The following topics how to use various features of rich edit and memo controls. Some of these features work with edit controls as well.

- Setting text alignment (see page 2166)
- Adding scrollbars at runtime (see page 2156)
- Adding the clipboard object (see page 2156)
- Selecting text (see page 2165)
- Selecting all text (see page 2165)
- Cutting (see page 2159)
- Deleting selected text (see page 2160)
- Disabling menu items (see page 2160)
- Providing a pop-up menu (see page 2164)
- Handling the OnPopup event (see page 2163)

3.2.4.12.33 Screen Scaling and ChangeScale

The ChangeScale method is dependent on the BorderStyle property of forms. When BorderStyle is Single, you cannot resize the form manually, and ChangeScale adjusts form size as would be expected. However, if a form's BorderStyle is Sizeable, ChangeScale unexpectedly fails, as if expecting the user to take care of sizing.

ChangeScale is sensitive to columns in a DBGrid that have been sized by the developer. ChangeScale typically fails on such columns. This can result in a DBGrid component and Form being adjusted by ChangeScale, but the Columns in the DBGrid not being resized.

When implementing either of these methods, it is relatively easy to perform the logical conversions from the built-in variant types. You must consider, however, the possibility that the variant to or from which you are casting may be another custom Variant type. To handle this situation, you can try casting to one of the built-in Variant types as an intermediate step.

You cannot remove the column sizing through the IDE. In Form Text mode, you need to remove the Width statement on the column definition.

3.2.4.13 Working with graphics and multimedia

Topics

Name	Description
Changing the Brush Style (see page 2175)	A brush style determines what pattern the canvas uses to fill shapes. It lets you specify various ways to combine the brush's color with any colors already on the canvas. The predefined styles include solid color, no color, and various line and hatch patterns. To change the style of a brush, set its Style property to one of the predefined values: bsBDiagonal, bsClear, bsCross, bsDiagCross, bsFDiagonal, bsHorizontal, bsSolid, or bsVertical. Cross-platform applications include the predefined values of bsDense1 through bsDense7. This example sets brush styles by sharing a click-event handler for a set of eight brush-style buttons. All eight buttons... more (see page 2175)

Overview of Graphics Programming (see page 2176)	In VCL applications, the graphics components defined in the Graphics unit encapsulate the Windows Graphics Device Interface (GDI), making it easy to add graphics to your Windows applications. To draw graphics in an application, you draw on an object's *canvas*, rather than directly on the object. The canvas is a property of the object, and is itself an object. A main advantage of the canvas object is that it handles resources effectively and it manages the device context for you, so your programs can use the same methods regardless of whether you are drawing on the screen,... more (see page 2176)
Working with Multimedia (see page 2177)	You can add multimedia components to your applications. To do this, you can use either the TAnimate component on the Win32 page or the TMediaPlayer component on the System category of the **Tool palette**. Use the animate component when you want to add silent video clips to your application. Use the media player component when you want to add audio and/or video clips to an application. This topic discusses: • Adding silent video clips to an application (see page 2179) • Adding audio and/or video clips to an application (see page 2177)
Adding Audio and/or Video Clips to an Application (see page 2177)	With the media player component, you can add audio and/or video clips to your application. It opens a media device and plays, stops, pauses, records, etc., the audio and/or video clips used by the media device. The media device may be hardware or software. **Note:** Audio support is not available in cross-platform applications.
Adding Silent Video Clips to an Application (see page 2179)	With the animation control, you can add silent video clips to your application:
Example of Adding Audio and/or Video Clips (VCL Only) (see page 2179)	This example runs an AVI video clip of a multimedia advertisement.
Example of Adding Silent Video Clips (see page 2180)	Suppose you want to display an animated logo as the first screen that appears when your application starts. After the logo finishes playing the screen disappears.
Adding a Field to a Form Object to Track Mouse Actions (see page 2181)	To track whether a mouse button was pressed, you must add an object field to the form object. When you add a component to a form, Delphi adds a field that represents that component to the form object, so that you can refer to the component by the name of its field. You can also add your own fields to forms by editing the type declaration in the form unit's header file. In the following example, the form needs to track whether the user has pressed a mouse button. To do that, it adds a Boolean field and sets its... more (see page 2181)
Adding an Image Control (see page 2181)	An image control is a container component that allows you to display your bitmap objects. You use an image control to hold a bitmap that is not necessarily displayed all the time, or which an application needs to use to generate other pictures. **Note:** Adding Graphics to Controls (see page 2154) shows how to use graphics in controls.
Changing the Brush Color (see page 2181)	A brush's color determines what color the canvas uses to fill shapes. To change the fill color, assign a value to the brush's *Color* property. Brush is used for background color in text and line drawing so you typically set the background color property. You can set the brush color just as you do the pen color, in response to a click on a color grid on the brush's toolbar :
Changing the Pen Color (see page 2182)	You can set the color of a pen as you would any other *Color* property at runtime. A pen's color determines the color of the lines the pen draws, including lines drawn as the boundaries of shapes, as well as other lines and polylines. To change the pen color, assign a value to the *Color* property of the pen. To let the user choose a new color for the pen, put a color grid on the pen's toolbar. A color grid can set both foreground and background colors. For a non-grid pen style, you must consider the background color, which... more (see page 2182)
Changing the Pen Mode (see page 2182)	A pen's *Mode* property lets you specify various ways to combine the pen's color with the color on the canvas. For example, the pen could always be black, be an inverse of the canvas background color, inverse of the pen color, and so on.
Changing the Pen Style (see page 2182)	A pen's *Style* property allows you to set solid lines, dashed lines, dotted lines, and so on. The task of setting the properties of pen is an ideal case for having different controls share same event handler to handle events. To determine which control actually got the event, you check the *Sender* parameter.

Changing the Pen Width (see page 2183)	A pen's width determines the thickness, in pixels, of the lines it draws. **Note:** When the thickness is greater than 1, Windows always draws solid lines, regardless of the value of the pen's *Style* property. To change the pen width, assign a numeric value to the pen's Width property. Suppose you have a scroll bar on the pen's toolbar to set width values for the pen. And suppose you want to update the label next to the scroll bar to provide feedback to the user. Using the scroll bar's position to determine the pen width, you update the pen width... more (see page 2183)
Changing the Tool with Speed Buttons (see page 2184)	Each drawing tool needs an associated *OnClick* event handler. Suppose your application had a toolbar button for each of four drawing tools: line, rectangle, ellipse, and rounded rectangle. You would attach the following event handlers to the *OnClick* events of the four drawing-tool buttons, setting *DrawingTool* to the appropriate value for each:
Common Properties and Methods of Canvas (see page 2184)	The following table lists the commonly used properties of the Canvas object. ***Common properties of the Canvas object***
Copying Graphics to the Clipboard (see page 2186)	You can copy any picture, including the contents of image controls, to the clipboard. Once on the clipboard, the picture is available to all applications. To copy a picture to the clipboard, assign the picture to the clipboard object using the *Assign* method. This code shows how to copy the picture from an image control named *Image* to the clipboard in response to a click on an **Edit ▶ Copy** menu item:
Cutting Graphics to the Clipboard (see page 2186)	Cutting a graphic to the clipboard is exactly like copying it, but you also erase the graphic from the source. To cut a graphic from a picture to the clipboard, first copy it to the clipboard, then erase the original. In most cases, the only issue with cutting is how to show that the original image is erased. Setting the area to white is a common solution, as shown in the following code that attaches an event handler to the *OnClick* event of the **Edit ▶ Cut** menu item:
Drawing Lines (see page 2187)	To draw a straight line on a canvas, use the LineTo method of the canvas. *LineTo* draws a line from the current pen position to the point you specify and makes the endpoint of the line the current position. The canvas draws the line using its pen. For example, the following method draws crossed diagonal lines across a form whenever the form is painted:
Drawing Lines and Polylines (see page 2187)	A canvas can draw straight lines and polylines. A straight line is just a line of pixels connecting two points. A polyline is a series of straight lines, connected end-to-end. The canvas draws all lines using its pen.
Drawing On a Graphic (see page 2187)	You don't need any components to manipulate your application's graphic objects. You can construct, draw on, save, and destroy graphic objects without ever drawing anything on screen. In fact, your applications rarely draw directly on a form. More often, an application operates on graphics and then uses an image control component to display the graphic on a form. Once you move the application's drawing to the graphic in the image control, it is easy to add printing, clipboard, and loading and saving operations for any graphic objects. graphic objects can be bitmap files, drawings, icons or whatever other graphics classes... more (see page 2187)
Drawing On the Bitmap (see page 2188)	To draw on a bitmap, use the image control's canvas and attach the mouse-event handlers to the appropriate events in the image control. Typically, you would use region operations (fills, rectangles, polylines, and so on). These are fast and efficient methods of drawing. An efficient way to draw images when you need to access individual pixels is to use the bitmap *ScanLine* property. For general-purpose usage, you can set up the bitmap pixel format to 24 bits and then treat the pointer returned from *ScanLine* as an array of RGB. Otherwise, you will need to know the native format of... more (see page 2188)
Drawing Polygons (see page 2189)	To draw a polygon with any number of sides on a canvas, call the *Polygon* method of the canvas. *Polygon* takes an array of points as its only parameter and connects the points with the pen, then connects the last point to the first to close the polygon. After drawing the lines, *Polygon* uses the brush to fill the area inside the polygon.
Drawing Polylines (see page 2189)	In addition to individual lines, the canvas can also draw polylines, which are groups of any number of connected line segments. To draw a polyline on a canvas, call the Polyline method of the canvas. The parameter passed to the *Polyline* method is an array of points. You can think of a polyline as performing a *MoveTo* on the first point and *LineTo* on each successive point. For drawing multiple lines, *Polyline* is faster than using the MoveTo method and the LineTo method because it eliminates a lot of call overhead.

Drawing Rectangles and Ellipses (see page 2189)	To draw a rectangle or ellipse on a canvas, call the canvas's Rectangle method or Ellipse method, passing the coordinates of a bounding rectangle. The *Rectangle* method draws the bounding rectangle; *Ellipse* draws an ellipse that touches all sides of the rectangle.
Drawing Rounded Rectangles (see page 2189)	To draw a rounded rectangle on a canvas, call the canvas's RoundRect method. The first four parameters passed to RoundRect are a bounding rectangle, just as for the Rectangle method or the Ellipse method. *RoundRect* takes two more parameters that indicate how to draw the rounded corners.
Drawing Shapes (see page 2190)	Canvases have methods for drawing different kinds of shapes. The canvas draws the outline of a shape with its pen, then fills the interior with its brush. The line that forms the border for the shape is controlled by the current *Pen* object. This topic describes: • Drawing rectangles and ellipses (see page 2189). • Drawing rounded rectangles. (see page 2189) • Drawing polygons (see page 2189).
Drawing Shapes (Code) (see page 2190)	Drawing shapes is just as easy as drawing lines. Each one takes a single statement; you just need the coordinates. Here's a rewrite of the *OnMouseUp* event handler that draws shapes for all four tools:
Getting the Pen Position (see page 2192)	The current drawing position—the position from which the pen begins drawing its next line—is called the pen position. The canvas stores its pen position in its PenPos property. Pen position affects the drawing of lines only; for shapes and text, you specify all the coordinates you need. To set the pen position, call the MoveTo method of the canvas. For example, the following code moves the pen position to the upper left corner of the canvas:
Handling Multiple Drawing Objects in Your Application (see page 2192)	Various drawing methods (rectangle, shape, line, and so on) are typically available on the toolbar and button panel. Applications can respond to clicks on speed buttons to set the desired drawing objects. This section describes how to: • Keep track of which drawing tool to use (see page 2193). • Change the tool with speed buttons (see page 2184). • Use drawing tools (see page 2206).
Keeping Track of Which Drawing Tool to Use (see page 2193)	A graphics program needs to keep track of what kind of drawing tool (such as a line, rectangle, ellipse, or rounded rectangle) a user might want to use at any given time. You could assign numbers to each kind of tool, but then you would have to remember what each number stands for. You can do that more easily by assigning mnemonic constant names to each number, but your code won"t be able to distinguish which numbers are in the proper range and of the right type. Fortunately, Delphi provides a means to handle both of these shortcomings. You can... more (see page 2193)
Loading a Picture from a File (see page 2194)	Your application should provide the ability to load a picture from a file if your application needs to modify the picture or if you want to store the picture outside the application so a person or another application can modify the picture. To load a graphics file into an image control, call the *LoadFromFile* method of the image control's *Picture* object. The following code gets a file name from an open picture file dialog box, and then loads that file into an image control named *Image*:
Loading and Saving Graphics Files (see page 2194)	Graphic images that exist only for the duration of one running of an application are of very limited value. Often, you either want to use the same picture every time, or you want to save a created picture for later use. The image component makes it easy to load pictures from a file and save them again. The components you use to load, save, and replace graphic images support many graphic formats including bitmap files, metafiles, glyphs, and so on. They also support installable graphic classes. The way to load and save graphics files is the similar to any other... more (see page 2194)
Making Scrollable Graphics (see page 2195)	The graphic need not be the same size as the form: it can be either smaller or larger. By adding a scroll box control to the form and placing the graphic image inside it, you can display graphics that are much larger than the form or even larger than the screen. To add a scrollable graphic first you add a *TScrollBox* component and then you add the image control.
Pasting Graphics from the Clipboard (see page 2195)	If the clipboard contains a bitmapped graphic, you can paste it into any image object, including image controls and the surface of a form.

Placing the Control (see page 2196)	You can place an image control anywhere on a form. If you take advantage of the image control's ability to size itself to its picture, you need to set the top left corner only. If the image control is a nonvisible holder for a bitmap, you can place it anywhere, just as you would a nonvisual component. If you drop the image control on a scroll box already aligned to the form's client area, this assures that the scroll box adds any scroll bars necessary to access offscreen portions of the image's picture. Then set the image control's properties.
Reading and Setting Pixels (see page 2196)	You will notice that every canvas has an indexed Pixels property that represents the individual colored points that make up the image on the canvas. You rarely need to access *Pixels* directly, it is available only for convenience to perform small actions such as finding or setting a pixel's color. **Note:** Setting and getting individual pixels is thousands of times slower than performing graphics operations on regions. Do not use the Pixel array property to access the image pixels of a general array. For high-performance access to image pixels, see the TBitmap.ScanLine property
Refining Line Drawing (see page 2196)	With fields in place to track various points, you can refine an application's line drawing.
Refreshing the Screen (see page 2196)	At certain times, the operating system determines that objects onscreen need to refresh their appearance, so it generates WM_PAINT messages on Windows, which the VCL routes to *OnPaint* events. If you have written an *OnPaint* event handler for that object, it is called when you use the *Refresh* method. The default name generated for the *OnPaint* event handler in a form is *FormPaint*. You may want to use the *Refresh* method at times to refresh a component or form. For example, you might call *Refresh* in the form's *OnResize* event handler to redisplay any graphics or if using the... more (see page 2196)
Replacing the Picture (see page 2197)	You can replace the picture in an image control at any time. If you assign a new graphic to a picture that already has a graphic, the new graphic replaces the existing one. To replace the picture in an image control, assign a new graphic to the image control's *Picture* object. Creating the new graphic is the same process you used to create the initial graphic , but you should also provide a way for the user to choose a size other than the default size used for the initial graphic. An easy way to provide that option is to... more (see page 2197)
Responding to a Mouse Move (see page 2198)	An *OnMouseMove* event occurs periodically when the user moves the mouse. The event goes to the object that was under the mouse pointer when the user pressed the button. This allows you to give the user some intermediate feedback by drawing temporary lines while the mouse moves. To respond to mouse movements, define an event handler for the *OnMouseMove* event. This example uses mouse-move events to draw intermediate shapes on a form while the user holds down the mouse button, thus providing some feedback to the user. The *OnMouseMove* event handler draws a line on a form to the location... more (see page 2198)
Responding to a Mouse-down Action (see page 2198)	Whenever the user presses a button on the mouse, an OnMouseDown event goes to the object the pointer is over. The object can then respond to the event. To respond to a mouse-down action, attach an event handler to the *OnMouseDown* event. The Code editor generates an empty handler for a mouse-down event on the form:
Responding to a Mouse-up Action (see page 2199)	An OnMouseUp event occurs whenever the user releases a mouse button. The event usually goes to the object the mouse cursor is over when the user presses the button, which is not necessarily the same object the cursor is over when the button is released. This enables you, for example, to draw a line as if it extended beyond the border of the form. To respond to mouse-up actions, define a handler for the *OnMouseUp* event.
Responding to the Mouse (see page 2199)	Your application can respond to the mouse actions: mouse-button down, mouse moved, and mouse-button up. It can also respond to a click (a complete press-and-release, all in one place) that can be generated by some kinds of keystrokes (such as pressing *Enter* in a modal dialog box). This topic describes: • What's in a mouse event (see page 2207). • Responding to a mouse-down action (see page 2198). • Responding to a mouse-up action (see page 2199). • Responding to a mouse move (see page 2198).

Rubber Banding Example (see page 2199)	This example describes the details of implementing the "rubber banding" effect in an graphics application that tracks mouse movements as the user draws a graphic at runtime. The example code covered in this topic is taken from a sample application located in the Demos\Doc\Graphexdirectory. The application draws lines and shapes on a window's canvas in response to clicks and drags: pressing a mouse button starts drawing, and releasing the button ends the drawing. To start with, the example code shows how to draw on the surface of the main form. Later examples demonstrate drawing on a bitmap. The following topics... more (see page 2199)
Saving a Picture to a File (see page 2200)	The picture object can load and save graphics in several formats, and you can create and register your own graphic-file formats so that picture objects can load and store them as well. To save the contents of an image control in a file, call the *SaveToFile* method of the image control's *Picture* object. The *SaveToFile* method requires the name of a file in which to save. If the picture is newly created, it might not have a file name, or a user might want to save an existing picture in a different file. In either case, the application needs to... more (see page 2200)
Setting the Brush Bitmap Property (see page 2201)	A brush's *Bitmap* property lets you specify a bitmap image for the brush to use as a pattern for filling shapes and other areas. The following example loads a bitmap from a file and assigns it to the Brush of the Canvas of Form1:
Setting the Initial Bitmap Size (see page 2201)	When you place an image control, it is simply a container. However, you can set the image control's Picture property at design time to contain a static graphic. The control can also load its picture from a file at runtime, as described in Loading And Saving Graphics Files (see page 2194).
Sharing Code Among Event Handlers (see page 2202)	Any time you find that many your event handlers use the same code, you can make your application more efficient by moving the repeated code into a routine that all event handlers can share.
Tracking Movement (see page 2202)	The problem with this example as the *OnMouseMove* event handler is currently written is that it draws the line to the current mouse position from the last *mouse position*, not from the original position. You can correct this by moving the drawing position to the origin point, then drawing to the current point:
Tracking the Origin Point (see page 2204)	When drawing lines, track the point where the line starts with the *Origin* field. *Origin* must be set to the point where the mouse-down event occurs, so the mouse-up event handler can use *Origin* to place the beginning of the line, as in this code:
Types of Graphic Objects (see page 2204)	The component library provides the following graphic objects. These objects have methods to draw on the canvas, which are described in Using Canvas methods to draw graphic objects (see page 2205) and to load and save to graphics files, as described in Loading and saving graphics files (see page 2194) ***Graphic object types***
Using Brushes (see page 2205)	The Brush property of a canvas controls the way you fill areas, including the interior of shapes. Filling an area with a brush is a way of changing a large number of adjacent pixels in a specified way. The brush has three properties you can manipulate: • Color property changes the fill color. • Style property changes the brush style. • Bitmap property uses a bitmap as a brush pattern. The values of these properties determine the way the canvas fills shapes or other areas. By default, every brush starts out white, with a solid style and no pattern bitmap. You can use... more (see page 2205)
Using Canvas Methods to Draw Graphic Objects (see page 2205)	This topic shows how to use some common methods to draw graphic objects. It covers: • Drawing lines and polylines. (see page 2187) • Drawing shapes. (see page 2190) • Drawing rounded rectangles. (see page 2189) • Drawing polygons. (see page 2189)

Using Drawing Tools (see page 2206)	Now that you can tell what tool to use, you must indicate how to draw the different shapes. The only methods that perform any drawing are the mouse-move and mouse-up handlers, and the only drawing code draws lines, no matter what tool is selected. To use different drawing tools, your code needs to specify how to draw, based on the selected tool. You add this instruction to each tool's event handler. This topic describes: • Drawing shapes (see page 2190). • Sharing code among event handlers (see page 2202).
Using Pens (see page 2206)	The Pen property of a canvas controls the way lines appear, including lines drawn as the outlines of shapes. Drawing a straight line is really just changing a group of pixels that lie between two points. The pen itself has four properties you can change: • Color property changes the pen color. • Width property changes the pen width. • Style property changes the pen style. • Mode property changes the pen mode. The values of these properties determine how the pen changes the pixels in the line. By default, every pen starts out black, with a width of 1 pixel, a solid style,... more (see page 2206)
Using the Clipboard with Graphics (see page 2206)	You can use the Windows clipboard to copy and paste graphics within your applications or to exchange graphics with other applications. The VCL's clipboard object makes it easy to handle different kinds of information, including graphics. Before you can use the clipboard object in your application, you must add the Clipbrd unit to the uses clause of any unit that needs to access clipboard data.
Using the Properties of the Canvas Object (see page 2207)	With the Canvas object, you can set the properties of a pen for drawing lines, a brush for filling shapes, a font for writing text, and an array of pixels to represent the image. This topic describes: • Using pens (see page 2206). • Using brushes (see page 2205). • Reading and setting pixels (see page 2196).
What's in a Mouse Event (see page 2207)	A mouse event occurs when a user moves the mouse in the user interface of an application. The VCL has three mouse events. ***Mouse events***
Working with Graphics and Multimedia: Overview (see page 2208)	Graphics and multimedia elements can add polish to your applications. You can introduce these features into your application in a variety of ways. To add graphical elements, you can insert pre-drawn pictures at design time, create them using graphical controls at design time, or draw them dynamically at runtime. To add multimedia capabilities, you can use special components that can play audio and video clips. This following topics describe how to enhance your applications by introducing graphics or multimedia elements: • Overview of Graphics Programming (see page 2176) • Working with multimedia (see page 2177)

3.2.4.13.1 Changing the Brush Style

A brush style determines what pattern the canvas uses to fill shapes. It lets you specify various ways to combine the brush's color with any colors already on the canvas. The predefined styles include solid color, no color, and various line and hatch patterns.

To change the style of a brush, set its Style property to one of the predefined values: bsBDiagonal, bsClear, bsCross, bsDiagCross, bsFDiagonal, bsHorizontal, bsSolid, or bsVertical. Cross-platform applications include the predefined values of

bsDense1 through bsDense7.

This example sets brush styles by sharing a click-event handler for a set of eight brush-style buttons. All eight buttons are selected, the **Object Inspector** ▸ **Events** ▸ **OnClick** is set, and the OnClick handler is named SetBrushStyle.

Here is the handler code:

```
procedure TForm1.SetBrushStyle(Sender: TObject);
begin
  with Canvas.Brush do
  begin
    if Sender = SolidBrush then Style := bsSolid
   else if Sender = ClearBrush then Style := bsClear
   else if Sender = HorizontalBrush then Style := bsHorizontal
   else if Sender = VerticalBrush then Style := bsVertical
   else if Sender = FDiagonalBrush then Style := bsFDiagonal
   else if Sender = BDiagonalBrush then Style := bsBDiagonal
   else if Sender = CrossBrush then Style := bsCross
   else if Sender = DiagCrossBrush then Style := bsDiagCross;
  end;
end;
void __fastcall TForm1::SetBrushStyle(TObject *Sender)
{
if (Sender == SolidBrush)
  Canvas->Brush->Style = bsSolid;
else if (Sender == ClearBrush)
  Canvas->Brush->Style = bsClear;
else if (Sender == HorizontalBrush)
  Canvas->Brush->Style = bsHorizontal;
else if (Sender == VerticalBrush)
  Canvas->Brush->Style = bsVertical;
else if (Sender == FDiagonalBrush)
  Canvas->Brush->Style = bsFDiagonal;
else if (Sender == BDiagonalBrush)
  Canvas->Brush->Style = bsBDiagonal;
else if (Sender == CrossBrush)
  Canvas->Brush->Style = bsCross;
else if (Sender == DiagCrossBrush)
  Canvas->Brush->Style = bsDiagCross;
}
void __fastcall TForm1::SetBrushStyle(TObject *Sender)
{
   if (Sender->InheritsFrom (__classid(TSpeedButton))
    Canvas->Brush->Style = (TBrushStyle) ((TSpeedButton *)Sender)->Tag;
}
```

Setting the Brush Bitmap Property (see page 2201)

3.2.4.13.2 Overview of Graphics Programming

In VCL applications, the graphics components defined in the Graphics unit encapsulate the Windows Graphics Device Interface (GDI), making it easy to add graphics to your Windows applications.

To draw graphics in an application, you draw on an object's *canvas*, rather than directly on the object. The canvas is a property of the object, and is itself an object. A main advantage of the canvas object is that it handles resources effectively and it manages the device context for you, so your programs can use the same methods regardless of whether you are drawing on the screen, to a printer, or on bitmaps or metafiles. Canvases are available only at runtime, so you do all your work with canvases by writing code.

Note: Since *TCanvas* is a wrapper resource manager around the Windows device context, you can also use all Windows GDI

functions on the canvas. The *Handle* property of the canvas is the device context Handle.

How graphic images appear in your application depends on the type of object whose canvas you draw on. If you are drawing directly onto the canvas of a control, the picture is displayed immediately. However, if you draw on an offscreen image such as a *TBitmap* canvas, the image is not displayed until a control copies from the bitmap onto the control's canvas. That is, when drawing bitmaps and assigning them to an image control, the image appears only when the control has an opportunity to process its *OnPaint* message (VCL applications).

When working with graphics, you often encounter the terms *drawing* and *painting*:

- Drawing is the creation of a single, specific graphic element, such as a line or a shape, with code. In your code, you tell an object to draw a specific graphic in a specific place on its canvas by calling a drawing method of the canvas.
- Painting is the creation of the entire appearance of an object. Painting usually involves drawing. That is, in response to *OnPaint* events, an object generally draws some graphics. An edit box, for example, paints itself by drawing a rectangle and then drawing some text inside. A shape control, on the other hand, paints itself by drawing a single graphic.

The following topics describe how to use graphics components to simplify your coding.

- Refreshing the screen (see page 2196)
- Types of graphic objects (see page 2204)
- Common properties and methods of canvases (see page 2184)
- Handling multiple drawing objects in an application (see page 2192)
- Drawing on a bitmap (see page 2187)
- Loading and saving graphics files (see page 2194)
- Using the Clipboard with Graphics (see page 2206)
- Rubber banding example (see page 2199)

See Also

Working with Multimedia (see page 2177)

3.2.4.13.3 Working with Multimedia

You can add multimedia components to your applications. To do this, you can use either the TAnimate component on the Win32 page or the TMediaPlayer component on the System category of the **Tool palette**. Use the animate component when you want to add silent video clips to your application. Use the media player component when you want to add audio and/or video clips to an application.

This topic discusses:

- Adding silent video clips to an application (see page 2179)
- Adding audio and/or video clips to an application (see page 2177)

See Also

Overview of Graphics Programming (see page 2176)

3.2.4.13.4 Adding Audio and/or Video Clips to an Application

With the media player component, you can add audio and/or video clips to your application. It opens a media device and plays, stops, pauses, records, etc., the audio and/or video clips used by the media device. The media device may be hardware or software.

Note: Audio support is not available in cross-platform applications.

To add an audio and/or video clip to an application:

1. Double-click the media player icon on the System category of the **Tool palette**. This automatically put a media player control on the form window in which you want the media feature.
2. Using the **Object Inspector**, select the Name*property* and enter a new name for your media player control. You will use this when you call the media player control. (Follow the standard rules for naming Delphi identifiers.) Always work directly with the **Object Inspector** when setting design time properties and creating event handlers.
3. Select the DeviceType property and choose the appropriate device type to open using the *AutoOpen* property or the *Open* method. (If *DeviceType* is dtAutoSelect the device type is selected based on the file extension of the media file specified by the *FileName* property.) For more information on device types and their functions, see the table below.
4. If the device stores its media in a file, specify the name of the media file using the *FileName* property. Select the FileName property, click the ellipsis (...) button, and choose a media file from any available local or network directories and click Open in the Open dialog. Otherwise, insert the hardware the media is stored in (disk, cassette, and so on) for the selected media device, at runtime.
5. Set the AutoOpen property to *True*. This way the media player automatically opens the specified device when the form containing the media player control is created at runtime. If *AutoOpen* is *False*, the device must be opened with a call to the Open method.
6. Set the AutoEnable property to *True* to automatically enable or disable the media player buttons as required at runtime; or, double-click the EnabledButtons property to set each button to *True* or *False* depending on which ones you want to enable or disable. The multimedia device is played, paused, stopped, and so on when the user clicks the corresponding button on the media player component. The device can also be controlled by the methods that correspond to the buttons (Play, Pause, Stop, Next, Previous, and so on).
7. Position the media player control bar on the form by either clicking and dragging it to the appropriate place on the form or by selecting the Align property and choosing the appropriate align position from the drop down list. If you want the media player to be invisible at runtime, set the Visible property to *False* and control the device by calling the appropriate methods (Play, Pause, Stop, Next, Previous, Step, Back, StartRecording, Eject).
8. Make any other changes to the TMediaPlayer control settings. For example, if the media requires a display window, set the Display property to the control that displays the media. If the device uses multiple tracks, set the Tracks property to the desired track.

Multimedia device types and their functions

Device Type	Software/Hardware used	Plays	Uses Tracks	Uses a Display Window
dtAVIVideo	AVI Video Player for Windows	AVI Video files	No	Yes
dtCDAudio	CD Audio Player for Windows or a CD Audio Player	CD Audio Disks	Yes	No
dtDAT	Digital Audio Tape Player	Digital Audio Tapes	Yes	No
dtDigitalVideo	Digital Video Player for Windows	AVI, MPG, MOV files	No	Yes
dtMMMovie	MM Movie Player	MM film	No	Yes
dtOverlay	Overlay device	Analog Video	No	Yes
dtScanner	Image Scanner	N/A for Play (scans images on Record)	No	No
dtSequencer	MIDI Sequencer for Windows	MIDI files	Yes	No
dtVCR	Video Cassette Recorder	Video Cassettes	No	Yes
dtWaveAudio	Wave Audio Player for Windows	WAV files	No	No

For more information on using the media player control, see the topic called Example of Adding Audio and/or Video Clips (see page 2179).

See Also

Example of Adding Audio and/or Video Clips (see page 2179)

Adding Silent Video Clips to an Application (see page 2179)

3.2.4.13.5 Adding Silent Video Clips to an Application

With the animation control, you can add silent video clips to your application:

To add silent videop clips

1. Double-click the *TAnimate* icon on the Win32 category of the **Tool palette**. This automatically puts an animation control on the form window in which you want to display the video clip.
2. Using the **Object Inspector**, select the Name property and enter a new *nam*e for your animation control. You will use this name when you call the animation control. (Follow the standard rules for naming Delphi identifiers). Always work directly with the **Object Inspector** when setting design time properties and creating event handlers.
3. Do one of the following:

- Select the CommonAVI property and choose one of the AVIs available from the drop-down list; or
- Select the resource of an AVI using the ResName or ResID properties. Use ResHandle to indicate the module that contains the resource identified by *ResName* or *ResID*; or
- Select the FileName property and click the ellipsis (...) button, choose an AVI file from any available local or network directories and click Open in the Open AVI or Open GIF dialog (Windows and cross-platform applications). This loads the AVI or GIF file into memory. If you want to display the first frame of the AVI or GIF clip on-screen until it is played using the *Active* property or the *Play* method, then set the Open property to *True*.

4. Set the Repetitions property to the number of times you want to the AVI or GIF clip to play. If this value is 0, then the sequence is repeated until the Stop method is called.
5. Make any other changes to the animation control settings. For example, *i*f you want to change the first frame displayed when animation control opens, then set the StartFrameproperty to the desired frame value.
6. Set the Active property to *True* using the drop-down list or write an event handler to run the AVI or GIF clip when a specific event takes place at runtime. For example, to activate the AVI or GIF clip when a button object is clicked, write the button's OnClick event specifying that. You may also call the Play method to specify when to play the AVI (VCL only).

   Note: If you make any changes to the form or any of the components on the form after setting *Active* to *True*, the *Active* property becomes *False* and you have to reset it to *True*. Do this either just before runtime or at runtime.

   For more information on using the animation control, see the topic called Example of adding silent video clips (see page 2180).

Example of Adding Silent Video Clips (see page 2180)

Adding Audio and/or Video Clips to an Application (see page 2177)

3.2.4.13.6 Example of Adding Audio and/or Video Clips (VCL Only)

This example runs an AVI video clip of a multimedia advertisement.

To run this example, create a new project and save the Unit1.pas file to FrmAd.pas and save the Project1.dpr file to DelphiAd.dpr. Then:

1. Double-click the media player icon on the System category of the **Tool palette**.
2. Using the **Object Inspector**, set the Name property of the media player to *VideoPlayer1*.
3. Select its DeviceType property and choose dtAVIVideo from the drop-down list.

4. Select its FileName property, click the ellipsis (...) button, locate and choose an AVI file. Click Open in the Open dialog.
5. Set its AutoOpen property to *True* and its Visible property to *False*.
6. Double-click the Animate icon from the Win32 category of the **Tool palette**. Set its AutoSize property to *False*, its Height property to 175 and Width property to 200. Click and drag the animation control to the top left corner of the form.
7. Click the media player to bring back focus to it. Select its Display property and choose Animate1 from the drop down list.
8. Click the form to bring focus to it and select its Name property and enter *Delphi_Ad*. Now resize the form to the size of the animation control.
9. Double-click the form's *OnActivate* event and write the following code to run the AVI video when the form is in focus:

```
VideoPlayer1.Play;
VideoPlayer1->Play();
```

Choose **Run** ▶ **Run** to execute the AVI video.

See Also

Adding Audio and/or Video Clips to an Application (see page 2177)

3.2.4.13.7 Example of Adding Silent Video Clips

Suppose you want to display an animated logo as the first screen that appears when your application starts. After the logo finishes playing the screen disappears.

To run this example, create a new project and save the Unit1.pas file as Frmlogo.pas and save the Project1.dpr file as Logo.dpr. Then:

1. Double-click the animate icon from the Win32 category of the **Tool palette**.
2. Using the **Object Inspector**, set its Name property to *Logo1*.
3. Select its FileName property, click the ellipsis (...) button, locate and choose an AVI file. Then click Open in the Open AVI dialog. This loads the AVI file into memory.
4. Position the animation control box on the form by clicking and dragging it to the top right hand side of the form.
5. Set its Repetitions property to 5.
6. Click the form to bring focus to it and set its Name property to *LogoForm1* and its Caption property to *Logo Window*. Now decrease the height of the form to right-center the animation control on it.
7. Double-click the form's *OnActivate* event and write the following code to run the AVI clip when the form is in focus at runtime:

```
Logo1.Active := True;
Logo1->Active = true;
```

8. Double-click the Label icon on the Standard category of the **Tool palette**. Select its Caption property and enter *Welcome to Cool Images 4.0*. Now select its Font property, click the ellipsis (...) button and choose Font Style: Bold, Size: 18, Color: Navy from the Font dialog and click OK. Click and drag the label control to center it on the form.
9. Click the animation control to bring focus back to it. Double-click its *OnStop* event and write the following code to close the form when the AVI file stops:

```
LogoForm1.Close;
LogoForm1->Close();
```

Select **Run** ▶ **Run** to execute the animated logo window.

Adding Silent Video Clips to an Application (see page 2179)

3.2.4.13.8 Adding a Field to a Form Object to Track Mouse Actions

To track whether a mouse button was pressed, you must add an object field to the form object. When you add a component to a form, Delphi adds a field that represents that component to the form object, so that you can refer to the component by the name of its field. You can also add your own fields to forms by editing the type declaration in the form unit's header file.

In the following example, the form needs to track whether the user has pressed a mouse button. To do that, it adds a Boolean field and sets its value when the user presses the mouse button.

To add a field to an object, edit the object's type definition, specifying the field identifier and type after the **public** directive at the bottom of the declaration.

Delphi "owns" any declarations before the **public** directive: that's where it puts the fields that represent controls and the methods that respond to events.

See Also

Responding to the Mouse (see page 2199)

Refining Line Drawing (see page 2196)

3.2.4.13.9 Adding an Image Control

An image control is a container component that allows you to display your bitmap objects. You use an image control to hold a bitmap that is not necessarily displayed all the time, or which an application needs to use to generate other pictures.

Note: Adding Graphics to Controls (see page 2154) shows how to use graphics in controls.

See Also

Placing the Control (see page 2196)

Making Scrollable Bitmaps (see page 2195)

Setting the Initial Bitmap Size (see page 2201)

Drawing On the Bitmap (see page 2188)

3.2.4.13.10 Changing the Brush Color

A brush's color determines what color the canvas uses to fill shapes. To change the fill color, assign a value to the brush's *Color* property. Brush is used for background color in text and line drawing so you typically set the background color property.

You can set the brush color just as you do the pen color, in response to a click on a color grid on the brush's toolbar :

```
procedure TForm1.BrushColorClick(Sender: TObject);
begin
Canvas.Brush.Color := BrushColor.ForegroundColor;
end;
void __fastcall TForm1::BrushColorClick(TObject *Sender)
{
  Canvas->Brush->Color = BrushColor->BackgroundColor;
}
```

See Also

Changing the Brush Style (see page 2175)

Setting the Brush Bitmap Property (see page 2201)

3.2.4.13.11 Changing the Pen Color

You can set the color of a pen as you would any other *Color* property at runtime. A pen's color determines the color of the lines the pen draws, including lines drawn as the boundaries of shapes, as well as other lines and polylines. To change the pen color, assign a value to the *Color* property of the pen.

To let the user choose a new color for the pen, put a color grid on the pen's toolbar. A color grid can set both foreground and background colors. For a non-grid pen style, you must consider the background color, which is drawn in the gaps between line segments. Background color comes from the Brush color property.

Since the user chooses a new color by clicking the grid, this code changes the pen's color in response to the *OnClick* event:

```
procedure TForm1.PenColorClick(Sender: TObject);
begin
Canvas.Pen.Color := PenColor.ForegroundColor;
end;
void __fastcall TForm1::PenColorClick(TObject *Sender)
{
  Canvas->Pen->Color = PenColor->ForegroundColor;
}
```

See Also

Changing the Pen Width (see page 2183)

Changing the Pen Style (see page 2182)

Changing the Pen Mode (see page 2182)

Getting the Pen Position (see page 2192)

3.2.4.13.12 Changing the Pen Mode

A pen's *Mode* property lets you specify various ways to combine the pen's color with the color on the canvas. For example, the pen could always be black, be an inverse of the canvas background color, inverse of the pen color, and so on.

See Also

Changing the Pen Color (see page 2182)

Changing the Pen Width (see page 2183)

Changing the Pen Style (see page 2182)

Getting the Pen Position (see page 2192)

3.2.4.13.13 Changing the Pen Style

A pen's *Style* property allows you to set solid lines, dashed lines, dotted lines, and so on.

The task of setting the properties of pen is an ideal case for having different controls share same event handler to handle events. To determine which control actually got the event, you check the *Sender* parameter.

To create one click-event handler for six pen-style buttons on a pen's toolbar, do the following:

1. Select all six pen-style buttons and select the **Object Inspector** ▶ **Events** ▶ **OnClick event** and in the Handler column, type `SetPenStyle`. The Code editor generates an empty click-event handler called *SetPenStyle* and attaches it to the *OnClick* events of all six buttons.
2. Fill in the click-event handler by setting the pen's style depending on the value of Sender, which is the control that sent the click event:

```
procedure TForm1.SetPenStyle(Sender: TObject);
begin
with Canvas.Pen do
begin
if Sender = SolidPen then Style := psSolid
else if Sender = DashPen then Style := psDash
else if Sender = DotPen then Style := psDot
else if Sender = DashDotPen then Style := psDashDot
else if Sender = DashDotDotPen then Style := psDashDotDot
else if Sender = ClearPen then Style := psClear;
end;
end;
void __fastcall TForm1::SetPenStyle(TObject *Sender)
{
  if (Sender == SolidPen)
    Canvas->Pen->Style = psSolid;
  else if (Sender == DashPen)
    Canvas->Pen->Style = psDash;
  else if (Sender == DotPen)
    Canvas->Pen->Style = psDot;
  else if (Sender == DashDotPen)
    Canvas->Pen->Style = psDashDot;
  else if (Sender == DashDotDotPen)
    Canvas->Pen->Style = psDashDotDot;
'  else if (Sender == ClearPen)
    Canvas->Pen->Style = psClear;
}
void __fastcall TForm1::SetPenStyle(TObject *Sender)
{
  if (Sender->InheritsFrom (__classid(TSpeedButton))
    Canvas->Pen->Style = (TPenStyle) ((TSpeedButton *)Sender)->Tag;
}
```

See Also

Changing the Pen Color (see page 2182)

Changing the Pen Width (see page 2183)

Changing the Pen Mode (see page 2182)

Getting the Pen Position (see page 2192)

3.2.4.13.14 Changing the Pen Width

A pen's width determines the thickness, in pixels, of the lines it draws.

Note: When the thickness is greater than 1, Windows always draws solid lines, regardless of the value of the pen's *Style* property.

To change the pen width, assign a numeric value to the pen's Width property.

Suppose you have a scroll bar on the pen's toolbar to set width values for the pen. And suppose you want to update the label next to the scroll bar to provide feedback to the user. Using the scroll bar's position to determine the pen width, you update the pen width every time the position changes.

This is how to handle the scroll bar's *OnChange* event:

```
procedure TForm1.PenWidthChange(Sender: TObject);
begin
Canvas.Pen.Width := PenWidth.Position;{ set the pen width directly }
PenSize.Caption := IntToStr(PenWidth.Position);{ convert to string for caption }
end;
void __fastcall TForm1::PenWidthChange(TObject *Sender)
{
```

```
  Canvas->Pen->Width = PenWidth->Position;         // set the pen width directly
  PenSize->Caption = IntToStr(PenWidth->Position); // convert to string
}
```

See Also

Changing the Pen Color (see page 2182)

Changing the Pen Style (see page 2182)

Changing the Pen Mode (see page 2182)

Getting the Pen Position (see page 2192)

3.2.4.13.15 Changing the Tool with Speed Buttons

Each drawing tool needs an associated *OnClick* event handler. Suppose your application had a toolbar button for each of four drawing tools: line, rectangle, ellipse, and rounded rectangle. You would attach the following event handlers to the *OnClick* events of the four drawing-tool buttons, setting *DrawingTool* to the appropriate value for each:

```
procedure TForm1.LineButtonClick(Sender: TObject);{ LineButton }
begin
DrawingTool := dtLine;
end;
procedure TForm1.RectangleButtonClick(Sender: TObject);{ RectangleButton }
begin
DrawingTool := dtRectangle;
end;
procedure TForm1.EllipseButtonClick(Sender: TObject);{ EllipseButton }
begin
DrawingTool := dtEllipse;
end;
procedure TForm1.RoundedRectButtonClick(Sender: TObject);{ RoundRectButton }
begin
DrawingTool := dtRoundRect;
end;
void __fastcall TForm1::LineButtonClick(TObject *Sender)  // LineButton
{
  DrawingTool = dtLine;
}
void __fastcall TForm1::RectangleButtonClick(TObject *Sender) // RectangleButton
{
  DrawingTool = dtRectangle;
}
void __fastcall TForm1::EllipseButtonClick(TObject *Sender)  // EllipseButton
{
  DrawingTool = dtEllipse;
}
void __fastcall TForm1::RoundedRectButtonClick(TObject *Sender) // RoundRectBtn
{
  DrawingTool = dtRoundRect;
}
```

Keeping Track of Which Drawing Tool to Use (see page 2193)

Using Drawing Tools (see page 2206)

3.2.4.13.16 Common Properties and Methods of Canvas

The following table lists the commonly used properties of the Canvas object.

Common properties of the Canvas object

Properties	Descriptions
Font	Specifies the font to use when writing text on the image. Set the properties of the TFont object to specify the font face, color, size, and style of the font.
Brush	Determines the color and pattern the canvas uses for filling graphical shapes and backgrounds. Set the properties of the TBrush object to specify the color and pattern or bitmap to use when filling in spaces on the canvas.
Pen	Specifies the kind of pen the canvas uses for drawing lines and outlining shapes. Set the properties of the TPen object to specify the color, style, width, and mode of the pen.
PenPos	Specifies the current drawing position of the pen.
Pixels	Specifies the color of the area of pixels within the current ClipRect.

These properties are described in more detail in Using the properties of the Canvas object (see page 2207).

Here is a list of several methods you can use:

Common methods of the Canvas object

Method	Descriptions
Arc	Draws an arc on the image along the perimeter of the ellipse bounded by the specified rectangle.
Chord	Draws a closed figure represented by the intersection of a line and an ellipse.
CopyRect	Copies part of an image from another canvas into the canvas.
Draw	Renders the graphic object specified by the Graphic parameter on the canvas at the location given by the coordinates (X, Y).
Ellipse	Draws the ellipse defined by a bounding rectangle on the canvas.
FillRect	Fills the specified rectangle on the canvas using the current brush.
FloodFill (VCL only)	Fills an area of the canvas using the current brush.
FrameRect (VCL only)	Draws a rectangle using the Brush of the canvas to draw the border.
LineTo	Draws a line on the canvas from PenPos to the point specified by X and Y, and sets the pen position to (X, Y).
MoveTo	Changes the current drawing position to the point (X,Y).
Pie	Draws a pie-shaped the section of the ellipse bounded by the rectangle (X1, Y1) and (X2, Y2) on the canvas.
Polygon	Draws a series of lines on the canvas connecting the points passed in and closing the shape by drawing a line from the last point to the first point.
Polyline	Draws a series of lines on the canvas with the current pen, connecting each of the points passed to it in Points.
Rectangle	Draws a rectangle on the canvas with its upper left corner at the point (X1, Y1) and its lower right corner at the point (X2, Y2). Use *Rectangle* to draw a box using Pen and fill it using Brush.
RoundRect	Draws a rectangle with rounded corners on the canvas.
StretchDraw	Draws a graphic on the canvas so that the image fits in the specified rectangle. The graphic image may need to change its magnitude or aspect ratio to fit.
TextHeight, TextWidth	Returns the height and width, respectively, of a string in the current font. Height includes leading between lines.
TextOut	Writes a string on the canvas, starting at the point (X,Y), and then updates the PenPos to the end of the string.
TextRect	Writes a string inside a region; any portions of the string that fall outside the region do not appear.

These methods are described in more detail in Using Canvas methods to draw graphic objects (see page 2205).

See Also

Refreshing the Screen (see page 2196)

Types of Graphic Objects (see page 2204)

3.2.4.13.17 Copying Graphics to the Clipboard

You can copy any picture, including the contents of image controls, to the clipboard. Once on the clipboard, the picture is available to all applications.

To copy a picture to the clipboard, assign the picture to the clipboard object using the *Assign* method.

This code shows how to copy the picture from an image control named *Image* to the clipboard in response to a click on an **Edit ▸ Copy** menu item:

```
procedure TForm1.Copy1Click(Sender: TObject);
begin
  Clipboard.Assign(Image.Picture)
end.
void __fastcall TForm1::Copy1Click(TObject *Sender)
{
  Clipboard()->Assign(Image->Picture);
}
```

See Also

Cutting Graphics to the Clipboard (see page 2186)

Pasting Graphics from the Clipboard (see page 2195)

3.2.4.13.18 Cutting Graphics to the Clipboard

Cutting a graphic to the clipboard is exactly like copying it, but you also erase the graphic from the source.

To cut a graphic from a picture to the clipboard, first copy it to the clipboard, then erase the original.

In most cases, the only issue with cutting is how to show that the original image is erased. Setting the area to white is a common solution, as shown in the following code that attaches an event handler to the *OnClick* event of the **Edit ▸ Cut** menu item:

```
procedure TForm1.Cut1Click(Sender: TObject);
var
ARect: TRect;
begin
Copy1Click(Sender);{ copy picture to clipboard }
with Image.Canvas do
begin
CopyMode := cmWhiteness;{ copy everything as white }
ARect := Rect(0, 0, Image.Width, Image.Height);{ get bitmap rectangle }
CopyRect(ARect, Image.Canvas, ARect);{ copy bitmap over itself }
CopyMode := cmSrcCopy;{ restore normal mode }
end;
end;
void __fastcall TForm1::Cut1Click(TObject *Sender)
{
  TRect ARect;
  Copy1Click(Sender);          // copy picture to clipboard
  Image->Canvas->CopyMode = cmWhiteness; // copy everything as white
  ARect = Rect(0, 0, Image->Width, Image->Height); // get dimensions of image
  Image->Canvas->CopyRect(ARect, Image->Canvas, ARect); // copy bitmap over self
  Image->Canvas->CopyMode = cmSrcCopy; // restore default mode
}
```

See Also

Copying Graphics to the Clipboard (see page 2186)

Pasting Graphics from the Clipboard (see page 2195)

3.2.4.13.19 Drawing Lines

To draw a straight line on a canvas, use the LineTo method of the canvas.

LineTo draws a line from the current pen position to the point you specify and makes the endpoint of the line the current position. The canvas draws the line using its pen.

For example, the following method draws crossed diagonal lines across a form whenever the form is painted:

```
procedure TForm1.FormPaint(Sender: TObject);
begin
with Canvas do
begin
MoveTo(0, 0);
LineTo(ClientWidth, ClientHeight);
MoveTo(0, ClientHeight);
LineTo(ClientWidth, 0);
end;
end;
void __fastcall TForm1::FormPaint(TObject *Sender)
{
  Canvas->MoveTo(0,0);
  Canvas->LineTo(ClientWidth, ClientHeight);
  Canvas->MoveTo(0, ClientHeight);
  Canvas->LineTo(ClientWidth, 0);
}
```

See Also

Drawing Polylines (see page 2189)

3.2.4.13.20 Drawing Lines and Polylines

A canvas can draw straight lines and polylines. A straight line is just a line of pixels connecting two points. A polyline is a series of straight lines, connected end-to-end. The canvas draws all lines using its pen.

See Also

Drawing Shapes (see page 2190)

Drawing Polylines (see page 2189)

3.2.4.13.21 Drawing On a Graphic

You don't need any components to manipulate your application's graphic objects. You can construct, draw on, save, and destroy graphic objects without ever drawing anything on screen. In fact, your applications rarely draw directly on a form. More often, an application operates on graphics and then uses an image control component to display the graphic on a form.

Once you move the application's drawing to the graphic in the image control, it is easy to add printing, clipboard, and loading and saving operations for any graphic objects. graphic objects can be bitmap files, drawings, icons or whatever other graphics classes that have been installed such as jpeg graphics.

Note: Because you are drawing on an offscreen image such as a *TBitmap* canvas, the image is not displayed until a control copies from a bitmap onto the control's canvas. That is, when drawing bitmaps and assigning them to an image control, the

image appears only when the control has an opportunity to process its paint message. But if you are drawing directly onto the canvas property of a control, the picture object is displayed immediately.

Handling Multiple Drawing Objects in Your Application (see page 2192)

Loading and Saving Graphics Files (see page 2194)

Using the Clipboard with Graphics (see page 2206)

Rubber Banding Example (see page 2199)

3.2.4.13.22 Drawing On the Bitmap

To draw on a bitmap, use the image control's canvas and attach the mouse-event handlers to the appropriate events in the image control. Typically, you would use region operations (fills, rectangles, polylines, and so on). These are fast and efficient methods of drawing.

An efficient way to draw images when you need to access individual pixels is to use the bitmap *ScanLine* property. For general-purpose usage, you can set up the bitmap pixel format to 24 bits and then treat the pointer returned from *ScanLine* as an array of RGB. Otherwise, you will need to know the native format of the *ScanLine* property. This example shows how to use *ScanLine* to get pixels one line at a time.

```
procedure TForm1.Button1Click(Sender: TObject);
// This example shows drawing directly to the Bitmap
var
x,y : integer;
Bitmap : TBitmap;
P : PByteArray;
begin
Bitmap := TBitmap.create;
try
Bitmap.LoadFromFile("C:\Program Files\Borland\Delphi 4\Images\Splash\256color\factory.bmp");
for y := 0 to Bitmap.height -1 do
begin
P := Bitmap.ScanLine[y];
for x := 0 to Bitmap.width -1 do
P[x] := y;
end;
canvas.draw(0,0,Bitmap);
finally
Bitmap.free;
end;
end;
void __fastcall TForm1::Button1Click(TObject *Sender)
{
Graphics::TBitmap *pBitmap = new Graphics::TBitmap();
// This example shows drawing directly to the Bitmap
Byte *ptr;
try
{
pBitmap->LoadFromFile("C:\\Program
Files\\Borland\\CBuilder\\Images\\Splash\\256color\\factory.bmp ");
for (int y = 0; y < pBitmap->Height; y++)
{
ptr = pBitmap->ScanLine[y];
for (int x = 0; x < pBitmap->Width; x++)
```

```
ptr[x] = (Byte)y;
}
Canvas->Draw(0,0,pBitmap);
}
catch (...)
{
ShowMessage("Could not load or alter bitmap");
}
delete pBitmap;
}
```

3.2.4.13.23 Drawing Polygons

To draw a polygon with any number of sides on a canvas, call the *Polygon* method of the canvas.

Polygon takes an array of points as its only parameter and connects the points with the pen, then connects the last point to the first to close the polygon. After drawing the lines, *Polygon* uses the brush to fill the area inside the polygon.

See Also

Drawing Rectangles and Ellipses (see page 2189)

Drawing Rounded Rectangles (see page 2189)

3.2.4.13.24 Drawing Polylines

In addition to individual lines, the canvas can also draw polylines, which are groups of any number of connected line segments.

To draw a polyline on a canvas, call the Polyline method of the canvas.

The parameter passed to the *Polyline* method is an array of points. You can think of a polyline as performing a *MoveTo* on the first point and *LineTo* on each successive point. For drawing multiple lines, *Polyline* is faster than using the MoveTo method and the LineTo method because it eliminates a lot of call overhead.

See Also

Drawing Lines (see page 2187)

3.2.4.13.25 Drawing Rectangles and Ellipses

To draw a rectangle or ellipse on a canvas, call the canvas's Rectangle method or Ellipse method, passing the coordinates of a bounding rectangle.

The *Rectangle* method draws the bounding rectangle; *Ellipse* draws an ellipse that touches all sides of the rectangle.

See Also

Drawing Rounded Rectangles (see page 2189)

Drawing Polygons (see page 2189)

3.2.4.13.26 Drawing Rounded Rectangles

To draw a rounded rectangle on a canvas, call the canvas's RoundRect method.

The first four parameters passed to RoundRect are a bounding rectangle, just as for the Rectangle method or the Ellipse method. *RoundRect* takes two more parameters that indicate how to draw the rounded corners.

See Also

Drawing Rectangles and Ellipses (see page 2189)

Drawing Polygons (see page 2189)

3.2.4.13.27 Drawing Shapes

Canvases have methods for drawing different kinds of shapes. The canvas draws the outline of a shape with its pen, then fills the interior with its brush. The line that forms the border for the shape is controlled by the current *Pen* object.

This topic describes:

- Drawing rectangles and ellipses (see page 2189).
- Drawing rounded rectangles. (see page 2189)
- Drawing polygons (see page 2189).

See Also

Drawing Lines and Polylines (see page 2187)

Using Pens (see page 2206)

Using Brushes (see page 2205)

3.2.4.13.28 Drawing Shapes (Code)

Drawing shapes is just as easy as drawing lines. Each one takes a single statement; you just need the coordinates.

Here's a rewrite of the *OnMouseUp* event handler that draws shapes for all four tools:

```
procedure TForm1.FormMouseUp(Sender: TObject; Button TMouseButton; Shift: TShiftState;
                             X,Y: Integer);
begin
case DrawingTool of
dtLine:
begin
Canvas.MoveTo(Origin.X, Origin.Y);
Canvas.LineTo(X, Y)
end;
dtRectangle: Canvas.Rectangle(Origin.X, Origin.Y, X, Y);
dtEllipse: Canvas.Ellipse(Origin.X, Origin.Y, X, Y);
dtRoundRect: Canvas.RoundRect(Origin.X, Origin.Y, X, Y,
(Origin.X - X) div 2, (Origin.Y - Y) div 2);
end;
Drawing := False;
end;
void __fastcall TForm1::FormMouseUp(TObject *Sender, TMouseButton Button,
                                    TShiftState Shift, int X, int Y){
  switch (DrawingTool)
  {
    case dtLine:
      Canvas->MoveTo(Origin.x, Origin.y);
      Canvas->LineTo(X, Y);
      break;
    case dtRectangle:
      Canvas->Rectangle(Origin.x, Origin.y, X, Y);
      break;
    case dtEllipse:
```

```
      Canvas->Ellipse(Origin.x, Origin.y, X, Y);
      break;
    case dtRoundRect:
      Canvas->Rectangle(Origin.x, Origin.y, X, Y, (Origin.x - X)/2,
                        (Origin.y - Y)/2);
      break;
  }
  Drawing = false;
}
```

Of course, you also need to update the *OnMouseMove* handler to draw shapes:

```
procedure TForm1.FormMouseMove(Sender: TObject; Shift: TShiftState; X, Y: Integer);
begin
if Drawing then
begin
Canvas.Pen.Mode := pmNotXor;
case DrawingTool of
dtLine: begin
Canvas.MoveTo(Origin.X, Origin.Y);
Canvas.LineTo(MovePt.X, MovePt.Y);
Canvas.MoveTo(Origin.X, Origin.Y);
Canvas.LineTo(X, Y);
end;
dtRectangle: begin
Canvas.Rectangle(Origin.X, Origin.Y, MovePt.X, MovePt.Y);
Canvas.Rectangle(Origin.X, Origin.Y, X, Y);
end;
dtEllipse: begin
Canvas.Ellipse(Origin.X, Origin.Y, X, Y);
Canvas.Ellipse(Origin.X, Origin.Y, X, Y);
end;
dtRoundRect: begin
Canvas.RoundRect(Origin.X, Origin.Y, X, Y,
(Origin.X - X) div 2, (Origin.Y - Y) div 2);
Canvas.RoundRect(Origin.X, Origin.Y, X, Y,
(Origin.X - X) div 2, (Origin.Y - Y) div 2);
end;
end;
MovePt := Point(X, Y);
end;
Canvas.Pen.Mode := pmCopy;
end;
void __fastcall TForm1::FormMouseMove(TObject *Sender, TMouseButton Button,
  TShiftState Shift, int X, int Y)
{
  if (Drawing)
  {
    Canvas->Pen->Mode = pmNotXor;        // use XOR mode to draw/erase
    switch (DrawingTool)
    {
      case dtLine:
        Canvas->MoveTo(Origin.x, Origin.y);
        Canvas->LineTo(MovePt.x, MovePt.y);
        Canvas->MoveTo(Origin.x, Origin.y);
        Canvas->LineTo(X, Y);
        break;
      case dtRectangle:
        Canvas->Rectangle(Origin.x, Origin.y, MovePt.x, MovePt.y);
        Canvas->Rectangle(Origin.x, Origin.y, X, Y);
        break;
      case dtEllipse:
        Canvas->Ellipse(Origin.x, Origin.y, MovePt.x, MovePt.y);
        Canvas->Ellipse(Origin.x, Origin.y, X, Y);
        break;
      case dtRoundRect:
        Canvas->Rectangle(Origin.x, Origin.y, MovePt.x, MovePt.y,
```

```
                        (Origin.x - MovePt.x)/2,(Origin.y - MovePt.y)/2);
          Canvas->Rectangle(Origin.x, Origin.y, X, Y,
                        (Origin.x - X)/2, (Origin.y - Y)/2);
          break;
      }
      MovePt = Point(X, Y);
    }
    Canvas->Pen->Mode = pmCopy;
  }
```

Typically, all the repetitious code that is in the above example would be in a separate routine. The next topic shows all the shape-drawing code in a single routine that all mouse-event handlers can call.

See Also

Sharing Code Among Event Handlers (see page 2202)

3.2.4.13.29 Getting the Pen Position

The current drawing position—the position from which the pen begins drawing its next line—is called the pen position. The canvas stores its pen position in its PenPos property. Pen position affects the drawing of lines only; for shapes and text, you specify all the coordinates you need.

To set the pen position, call the MoveTo method of the canvas. For example, the following code moves the pen position to the upper left corner of the canvas:

```
Canvas.MoveTo(0, 0);
Canvas->MoveTo(0, 0);
```

Note: Drawing a line with the LineTo method also moves the current position to the endpoint of the line.

3.2.4.13.30 Handling Multiple Drawing Objects in Your Application

Various drawing methods (rectangle, shape, line, and so on) are typically available on the toolbar and button panel. Applications can respond to clicks on speed buttons to set the desired drawing objects. This section describes how to:

- Keep track of which drawing tool to use (see page 2193).
- Change the tool with speed buttons (see page 2184).
- Use drawing tools (see page 2206).

3.2.4.13.31 Keeping Track of Which Drawing Tool to Use

A graphics program needs to keep track of what kind of drawing tool (such as a line, rectangle, ellipse, or rounded rectangle) a user might want to use at any given time.

You could assign numbers to each kind of tool, but then you would have to remember what each number stands for. You can do that more easily by assigning mnemonic constant names to each number, but your code won"t be able to distinguish which numbers are in the proper range and of the right type. Fortunately, Delphi provides a means to handle both of these shortcomings. You can declare an enumerated type.

An enumerated type is really just a shorthand way of assigning sequential values to constants. Since it's also a type declaration, you can use Delphi's type-checking to ensure that you assign only those specific values.

To declare an enumerated type, use the reserved work type, followed by an identifier for the type, then an equal sign, and the identifiers for the values in the type in parentheses, separated by commas.

For example, the following code declares an enumerated type for each drawing tool available in a graphics application:

```
type
TDrawingTool = (dtLine, dtRectangle, dtEllipse, dtRoundRect);
typedef enum {dtLine, dtRectangle, dtEllipse, dtRoundRect} TDrawingTool;
```

By convention, type identifiers begin with the letter *T*, and groups of similar constants (such as those making up an enumerated type) begin with a 2-letter prefix (such as *dt* for "drawing tool").

The declaration of the TDrawingTool type is equivalent to declaring a group of constants:

```
const
  dtLine = 0;
  dtRectangle = 1;
  dtEllipse = 2;
  dtRoundRect = 3;
```

The main difference is that by declaring the enumerated type, you give the constants not just a value, but also a type, which enables you to use the Delphi language's type-checking to prevent many errors. A variable of type *TDrawingTool* can be assigned only one of the constants dtLine..dtRoundRect. Attempting to assign some other number (even one in the range 0..3) generates a compile-time error.

In the following code, a field added to a form keeps track of the form's drawing tool:

```
type
TDrawingTool = (dtLine, dtRectangle, dtEllipse, dtRoundRect);
TForm1 = class(TForm)
...{ method declarations }
public
Drawing: Boolean;
Origin, MovePt: TPoint;
DrawingTool: TDrawingTool;{ field to hold current tool }
end;
enum TDrawingTool {dtLine, dtRectangle, dtEllipse, dtRoundRect};
class TForm1 : public TForm
{
__published:  // IDE-managed Components
  void __fastcall FormMouseDown(TObject *Sender, TMouseButton Button,
  TShiftState Shift, int X, int Y);
  void __fastcall FormMouseMove(TObject *Sender, TShiftState Shift, int X,
  int Y);
  void __fastcall FormMouseUp(TObject *Sender, TMouseButton Button,
  TShiftState Shift, int X, int Y);
private:
public:
```

```
    __fastcall TForm1(TComponent* Owner);
    bool Drawing;  //field to track whether button was pressed
    TDrawingTool DrawingTool;  // field to hold current tool
};
```

3.2.4.13.32 Loading a Picture from a File

Your application should provide the ability to load a picture from a file if your application needs to modify the picture or if you want to store the picture outside the application so a person or another application can modify the picture.

To load a graphics file into an image control, call the *LoadFromFile* method of the image control's *Picture* object.

The following code gets a file name from an open picture file dialog box, and then loads that file into an image control named *Image*:

```
procedure TForm1.Open1Click(Sender: TObject);
begin
if OpenPictureDialog1.Execute then
begin
CurrentFile := OpenPictureDialog1.FileName;
Image.Picture.LoadFromFile(CurrentFile);
end;
end;
void __fastcall TForm1::Open1Click(TObject *Sender)
{
  if (OpenPictureDialog1->Execute())
  {
    CurrentFile = OpenPictureDialog1->FileName;
    Image->Picture->LoadFromFile(CurrentFile);
  }
}
```

Replacing the Picture (see page 2197)

3.2.4.13.33 Loading and Saving Graphics Files

Graphic images that exist only for the duration of one running of an application are of very limited value. Often, you either want to use the same picture every time, or you want to save a created picture for later use. The image component makes it easy to load pictures from a file and save them again.

The components you use to load, save, and replace graphic images support many graphic formats including bitmap files, metafiles, glyphs, and so on. They also support installable graphic classes.

The way to load and save graphics files is the similar to any other files and is described in these topics:

- Loading a picture from a file. (see page 2194)
- Saving a picture to a file. (see page 2200)
- Replacing the picture. (see page 2197)

Rubber Banding Example (see page 2199)

3.2.4.13.34 Making Scrollable Graphics

The graphic need not be the same size as the form: it can be either smaller or larger. By adding a scroll box control to the form and placing the graphic image inside it, you can display graphics that are much larger than the form or even larger than the screen. To add a scrollable graphic first you add a *TScrollBox* component and then you add the image control.

See Also

Adding an Image Control (see page 2181)

3.2.4.13.35 Pasting Graphics from the Clipboard

If the clipboard contains a bitmapped graphic, you can paste it into any image object, including image controls and the surface of a form.

To paste a graphic from the clipboard:

1. Call the clipboard's HasFormat method (VCL applications) to see whether the clipboard contains a graphic. HasFormat is a Boolean function. It returns *True* if the clipboard contains an item of the type specified in the parameter. To test for graphics on the Windows platform, you pass *CF_BITMAP*.
2. Assign the clipboard to the destination.

   Note: The following VCL code shows how to paste a picture from the clipboard into an image control in response to a click on an Edit->Paste

   menu item:

```
procedure TForm1.PasteButtonClick(Sender: TObject);
var
Bitmap: TBitmap;
begin
if Clipboard.HasFormat(CF_BITMAP) then { is there a bitmap on the Windows clipboard? )
begin
Image1.Picture.Bitmap.Assign(Clipboard);
 end;
end;
void __fastcall TForm1::Paste1Click(TObject *Sender)
{
Graphics::TBitmap *Bitmap;
if (Clipboard()->HasFormat(CF_BITMAP)){
Image1->Picture->Bitmap->Assign(Clipboard());
  }
}
```

The graphic on the clipboard could come from this application, or it could have been copied from another application, such as Microsoft Paint. You do not need to check the clipboard format in this case because the paste menu should be disabled when the clipboard does not contain a supported format.

See Also

Copying Graphics to the Clipboard (see page 2186)

Cutting Graphics to the Clipboard (see page 2186)

3.2.4.13.36 Placing the Control

You can place an image control anywhere on a form. If you take advantage of the image control's ability to size itself to its picture, you need to set the top left corner only. If the image control is a nonvisible holder for a bitmap, you can place it anywhere, just as you would a nonvisual component.

If you drop the image control on a scroll box already aligned to the form's client area, this assures that the scroll box adds any scroll bars necessary to access offscreen portions of the image's picture. Then set the image control's properties.

See Also

Setting the Initial Bitmap Size (see page 2201)

Drawing On the Bitmap (see page 2188)

3.2.4.13.37 Reading and Setting Pixels

You will notice that every canvas has an indexed Pixels property that represents the individual colored points that make up the image on the canvas. You rarely need to access *Pixels* directly, it is available only for convenience to perform small actions such as finding or setting a pixel's color.

Note: Setting and getting individual pixels is thousands of times slower than performing graphics operations on regions. Do not use the Pixel array property to access the image pixels of a general array. For high-performance access to image pixels, see the TBitmap.ScanLine property

Using Pens (see page 2206)

Using Brushes (see page 2205)

3.2.4.13.38 Refining Line Drawing

With fields in place to track various points, you can refine an application's line drawing.

See Also

Responding to the Mouse (see page 2199)

Adding a Field to a Form Object to Track Mouse Actions (see page 2181)

3.2.4.13.39 Refreshing the Screen

At certain times, the operating system determines that objects onscreen need to refresh their appearance, so it generates WM_PAINT messages on Windows, which the VCL routes to *OnPaint* events. If you have written an *OnPaint* event handler for that object, it is called when you use the *Refresh* method. The default name generated for the *OnPaint* event handler in a form is *FormPaint*. You may want to use the *Refresh* method at times to refresh a component or form. For example, you might call *Refresh* in the form's *OnResize* event handler to redisplay any graphics or if using the VCL, you want to paint a background on a form.

While some operating systems automatically handle the redrawing of the client area of a window that has been invalidated,

Windows does not. In the Windows operating system anything drawn on the screen is permanent. When a form or control is temporarily obscured, for example during window dragging, the form or control must repaint the obscured area when it is re-exposed. For more information about the WM_PAINT message, see the Windows online Help.

If you use the *TImage* control to display a graphical image on a form, the painting and refreshing of the graphic contained in the *TImage* is handled automatically. The *Picture* property specifies the actual bitmap, drawing, or other graphic object that *TImage* displays. You can also set the *Proportional* property to ensure that the image can be fully displayed in the image control without any distortion. Drawing on a *TImage* creates a persistent image. Consequently, you do not need to do anything to redraw the contained image. In contrast, *TPaintBox*'s canvas maps directly onto the screen device (VCL applications), so that anything drawn to the *PaintBox*'s canvas is transitory. This is true of nearly all controls, including the form itself. Therefore, if you draw or paint on a *TPaintBox* in its constructor, you will need to add that code to your *OnPaint* event handler in order for the image to be repainted each time the client area is invalidated.

Common Properties and Methods of Canvas (see page 2184)

Types of Graphic Objects (see page 2204)

3.2.4.13.40 Replacing the Picture

You can replace the picture in an image control at any time. If you assign a new graphic to a picture that already has a graphic, the new graphic replaces the existing one.

To replace the picture in an image control, assign a new graphic to the image control's *Picture* object.

Creating the new graphic is the same process you used to create the initial graphic , but you should also provide a way for the user to choose a size other than the default size used for the initial graphic. An easy way to provide that option is to present a dialog box.

With such a dialog box in your project, add it to the uses clause in the unit for your main form. You can then attach an event handler to the **File ▶ New** menu item's OnClick event. Here's an example:

```
procedure TForm1.New1Click(Sender: TObject);
var
Bitmap: TBitmap;{ temporary variable for the new bitmap }
begin
with NewBMPForm do
begin
ActiveControl := WidthEdit;{ make sure focus is on width field }
WidthEdit.Text := IntToStr(Image.Picture.Graphic.Width);{ use current dimensions... }
HeightEdit.Text := IntToStr(Image.Picture.Graphic.Height);{ ...as default }
if ShowModal <> idCancel then{ continue if user doesn"t cancel dialog box }
begin
Bitmap := TBitmap.Create;{ create fresh bitmap object }
Bitmap.Width := StrToInt(WidthEdit.Text);{ use specified width }
Bitmap.Height := StrToInt(HeightEdit.Text);{ use specified height }
Image.Picture.Graphic := Bitmap;{ replace graphic with new bitmap }
CurrentFile := "";{ indicate unnamed file }
     Bitmap.Free;
end;
end;
end;
void __fastcall TForm1::New1Click(TObject *Sender)
{
Graphics::TBitmap *Bitmap;
  // make sure focus is on width field
 NewBMPForm->ActiveControl = NewBMPForm->WidthEdit;
  // initialize to current dimensions as default ...
     NewBMPForm->WidthEdit->Text = IntToStr(Image->Picture->Graphic->Width);
NewBMPForm->HeightEdit->Text = IntToStr(Image->Picture->Graphic->Height);
```

```
  if (NewBMPForm->ShowModal() != IDCANCEL){        // if user does not cancel dialog...
Bitmap = new Graphics::TBitmap();             // create a new bitmap object
    // use specified dimensions
     Bitmap->Width = StrToInt(NewBMPForm->WidthEdit->Text);
Bitmap->Height = StrToInt(NewBMPForm->HeightEdit->Text);
Image->Picture->Graphic = Bitmap;            // replace graphic with new bitmap
CurrentFile = EmptyStr;                      //indicate unnamed file
        delete Bitmap;
}
}
```

Note: Assigning a new bitmap to the picture object's Graphic property causes the picture object to copy the new graphic, but it does not take ownership of it. The picture object maintains its own internal graphic object. Because of this, the previous code frees the bitmap object after making the assignment.

Loading a Picture from a File (see page 2194)

Saving a Picture to a File (see page 2200)

3.2.4.13.41 Responding to a Mouse Move

An *OnMouseMove* event occurs periodically when the user moves the mouse. The event goes to the object that was under the mouse pointer when the user pressed the button. This allows you to give the user some intermediate feedback by drawing temporary lines while the mouse moves.

To respond to mouse movements, define an event handler for the *OnMouseMove* event. This example uses mouse-move events to draw intermediate shapes on a form while the user holds down the mouse button, thus providing some feedback to the user. The *OnMouseMove* event handler draws a line on a form to the location of the *OnMouseMove* event:

```
procedure TForm1.FormMouseMove(Sender: TObject;Button: TMouseButton;
Shift: TShiftState; X, Y: Integer);
begin
Canvas.LineTo(X, Y);{ draw line to current position }
end;
void __fastcall TForm1::FormMouseMove(TObject *Sender, TMouseButton Button,
  TShiftState Shift, int X, int Y)
{
  Canvas->LineTo(X, Y);
}
```

With this code, moving the mouse over the form causes drawing to follow the mouse, even before the mouse button is pressed.

Mouse-move events occur even when you haven't pressed the mouse button.

If you want to track whether there is a mouse button pressed, you need to add an object field to the form object.

See Also

What's in a Mouse Event (see page 2207)

Responding to a Mouse-down Action (see page 2198)

Responding to a Mouse-up Action (see page 2199)

3.2.4.13.42 Responding to a Mouse-down Action

Whenever the user presses a button on the mouse, an OnMouseDown event goes to the object the pointer is over. The object can then respond to the event.

To respond to a mouse-down action, attach an event handler to the *OnMouseDown* event.

The Code editor generates an empty handler for a mouse-down event on the form:

```
procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;
Shift: TShiftState; X, Y: Integer);
begin
end;
void __fastcall TForm1::FormMouseDown(TObject *Sender, TMouseButton Button,
  TShiftState Shift, int X, int Y)
{
}
```

See Also

What's in a Mouse Event (see page 2207)

Responding to a Mouse-up Action (see page 2199)

Responding to a Mouse Move (see page 2198)

3.2.4.13.43 Responding to a Mouse-up Action

An OnMouseUp event occurs whenever the user releases a mouse button. The event usually goes to the object the mouse cursor is over when the user presses the button, which is not necessarily the same object the cursor is over when the button is released. This enables you, for example, to draw a line as if it extended beyond the border of the form.

To respond to mouse-up actions, define a handler for the *OnMouseUp* event.

See Also

What's in a Mouse Event (see page 2207)

Responding to a Mouse-down Action (see page 2198)

Responding to a Mouse Move (see page 2198)

3.2.4.13.44 Responding to the Mouse

Your application can respond to the mouse actions: mouse-button down, mouse moved, and mouse-button up. It can also respond to a click (a complete press-and-release, all in one place) that can be generated by some kinds of keystrokes (such as pressing *Enter* in a modal dialog box).

This topic describes:

- What's in a mouse event (see page 2207).
- Responding to a mouse-down action (see page 2198).
- Responding to a mouse-up action (see page 2199).
- Responding to a mouse move (see page 2198).

What's in a Mouse Event (see page 2207)

3.2.4.13.45 Rubber Banding Example

This example describes the details of implementing the "rubber banding" effect in an graphics application that tracks mouse movements as the user draws a graphic at runtime. The example code covered in this topic is taken from a sample application

located in the Demos\Doc\Graphexdirectory. The application draws lines and shapes on a window's canvas in response to clicks and drags: pressing a mouse button starts drawing, and releasing the button ends the drawing.

To start with, the example code shows how to draw on the surface of the main form. Later examples demonstrate drawing on a bitmap.

The following topics describe the example:

- Responding to the mouse (see page 2199).
- Adding a field to a form object to track mouse actions (see page 2181).
- Refining line drawing (see page 2196).

Drawing on a Bitmap (see page 2188)

Loading and Saving Graphics Files (see page 2194)

Using the Clipboard with Graphics (see page 2206)

3.2.4.13.46 Saving a Picture to a File

The picture object can load and save graphics in several formats, and you can create and register your own graphic-file formats so that picture objects can load and store them as well.

To save the contents of an image control in a file, call the *SaveToFile* method of the image control's *Picture* object.

The *SaveToFile* method requires the name of a file in which to save. If the picture is newly created, it might not have a file name, or a user might want to save an existing picture in a different file. In either case, the application needs to get a file name from the user before saving, as shown in the next topic.

The following pair of event handlers, attached to the **File▶Save** and **File▶Save As** menu items, respectively, handle the resaving of named files, saving of unnamed files, and saving existing files under new names.

```
procedure TForm1.Save1Click(Sender: TObject);
begin
if CurrentFile <> '' then
Image.Picture.SaveToFile(CurrentFile){ save if already named }
else SaveAs1Click(Sender);{ otherwise get a name }
end;
procedure TForm1.Saveas1Click(Sender: TObject);
begin
if SaveDialog1.Execute then{ get a file name }
begin
CurrentFile := SaveDialog1.FileName;{ save the user-specified name }
Save1Click(Sender);{ then save normally }
end;
end;
void __fastcall TForm1::Save1Click(TObject *Sender)
{
  if (!CurrentFile.IsEmpty())
    Image->Picture->SaveToFile(CurrentFile);   // save if already named
else SaveAs1Click(Sender);                     // otherwise get a name
}
void __fastcall TForm1::SaveAs1Click(TObject *Sender)
```

```
{
  if (SaveDialog1->Execute())              // get a file name
  {
    CurrentFile = SaveDialog1->FileName;  // save user-specified name
    Save1Click(Sender);                   // then save normally
  }
}
```

3.2.4.13.47 Setting the Brush Bitmap Property

A brush's *Bitmap* property lets you specify a bitmap image for the brush to use as a pattern for filling shapes and other areas.

The following example loads a bitmap from a file and assigns it to the Brush of the Canvas of Form1:

```
var
Bitmap: TBitmap;
begin
Bitmap := TBitmap.Create;
try
Bitmap.LoadFromFile('MyBitmap.bmp');
Form1.Canvas.Brush.Bitmap := Bitmap;
Form1.Canvas.FillRect(Rect(0,0,100,100));
finally
Form1.Canvas.Brush.Bitmap := nil;
Bitmap.Free;
end;
end;
BrushBmp->LoadFromFile("MyBitmap.bmp");
Form1->Canvas->Brush->Bitmap = BrushBmp;
Form1->Canvas->FillRect(Rect(0,0,100,100));
```

Note: The brush does not assume ownership of a bitmap object assigned to its *Bitmap* property. You must ensure that the Bitmap object remains valid for the lifetime of the Brush, and you must free the Bitmap object yourself afterwards.

See Also

Changing the Brush Color (see page 2181)

Changing the Brush Style (see page 2175)

3.2.4.13.48 Setting the Initial Bitmap Size

When you place an image control, it is simply a container. However, you can set the image control's Picture property at design time to contain a static graphic. The control can also load its picture from a file at runtime, as described in Loading And Saving Graphics Files (see page 2194).

To create a blank bitmap when the application starts

1. Attach a handler to the *OnCreate* event for the form that contains the image.
2. Create a bitmap object, and assign it to the image control's *Picture.Graphic* property.

In this example, the image is in the application's main form, *Form1*, so the code attaches a handler to *Form1's OnCreate* event:

```
procedure TForm1.FormCreate(Sender: TObject);
var
Bitmap: TBitmap;{ temporary variable to hold the bitmap }
begin
```

```
Bitmap := TBitmap.Create;{ construct the bitmap object }
  Bitmap.Width := 200;{ assign the initial width... }
  Bitmap.Height := 200;{ ...and the initial height }
  Image.Picture.Graphic := Bitmap;{ assign the bitmap to the image control }
  Bitmap.Free; {We are done with the bitmap, so free it }
end;
void __fastcall TForm1::FormCreate(TObject *Sender)
{
  Graphics::TBitmap *Bitmap = new Graphics::TBitmap();   // create the bitmap object
  Bitmap->Width = 200;               // assign the initial width...
  Bitmap->Height = 200;              // ...and the initial height
  Image->Picture->Graphic = Bitmap;  // assign the bitmap to the image control
  delete Bitmap;                     // free the bitmap object
}
```

Assigning the bitmap to the picture's *Graphic* property copies the bitmap to the picture object. However, the picture object does not take ownership of the bitmap, so after making the assignment, you must free it.

If you run the application now, you see that client area of the form has a white region, representing the bitmap. If you size the window so that the client area cannot display the entire image, you'll see that the scroll box automatically shows scroll bars to allow display of the rest of the image. But if you try to draw on the image, you don't get any graphics, because the application is still drawing on the form, which is now behind the image and the scroll box.

Placing the Control (see page 2196)

Drawing On the Bitmap (see page 2188)

3.2.4.13.49 Sharing Code Among Event Handlers

Any time you find that many your event handlers use the same code, you can make your application more efficient by moving the repeated code into a routine that all event handlers can share.

To add a method to a form:

1. Add the method declaration to the form object. You can add the declaration in either the **public** or **private** parts at the end of the form object's declaration. If the code is just sharing the details of handling some events, it's probably safest to make the shared method **private**.
2. Write the method implementation in the implementation part of the form unit.

The header for the method implementation must match the declaration exactly, with the same parameters in the same order.

See Also

Drawing Shapes (see page 2190)

3.2.4.13.50 Tracking Movement

The problem with this example as the *OnMouseMove* event handler is currently written is that it draws the line to the current mouse position from the last *mouse position*, not from the original position. You can correct this by moving the drawing position to the origin point, then drawing to the current point:

```
procedure TForm1.FormMouseMove(Sender: TObject;Button: TMouseButton;
Shift: TShiftState; X, Y: Integer);
begin
if Drawing then
begin
Canvas.MoveTo(Origin.X, Origin.Y);{ move pen to starting point }
Canvas.LineTo(X, Y);
end;
```

```
end;
void __fastcall TForm1::FormMouseMove(TObject *Sender, TMouseButton Button,
  TShiftState Shift, int X, int Y)
{
  if (Drawing)
  {
    Canvas->MoveTo(Origin.x, Origin.y);  // move pen to starting point
    Canvas->LineTo(X, Y);
  }
}
```

The above tracks the current mouse position, but the intermediate lines do not go away, so you can hardly see the final line. The example needs to erase each line before drawing the next one, by keeping track of where the previous one was. The *MovePt* field allows you to do this.

MovePt must be set to the endpoint of each intermediate line, so you can use *MovePt* and *Origin* to erase that line the next time a line is drawn:

```
procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;
Shift: TShiftState; X, Y: Integer);
begin
Drawing := True;
Canvas.MoveTo(X, Y);
Origin := Point(X, Y);
MovePt := Point(X, Y);{ keep track of where this move was }
end;
procedure TForm1.FormMouseMove(Sender: TObject;Button: TMouseButton;
Shift: TShiftState; X, Y: Integer);
begin
if Drawing then
begin
Canvas.Pen.Mode := pmNotXor;{ use XOR mode to draw/erase }
Canvas.MoveTo(Origin.X, Origin.Y);{ move pen back to origin }
Canvas.LineTo(MovePt.X, MovePt.Y);{ erase the old line }
Canvas.MoveTo(Origin.X, Origin.Y);{ start at origin again }
Canvas.LineTo(X, Y);{ draw the new line }
end;
MovePt := Point(X, Y);{ record point for next move }
Canvas.Pen.Mode := pmCopy;
end;
void __fastcall TForm1::FormMouseDown(TObject *Sender, TMouseButton Button,
  TShiftState Shift, int X, int Y)
{
  Drawing = true;            // set the Drawing flag
  Canvas->MoveTo(X, Y);      // set pen position
  Origin = Point(X, Y);      // record where the line starts
  MovePt = Point(X, Y);      // record last endpoint
}
void __fastcall TForm1::FormMouseMove(TObject *Sender, TMouseButton Button,
  TShiftState Shift, int X, int Y)
{
  if (Drawing)
  {
    Canvas->Pen->Mode = pmNotXor;        // use XOR mode to draw/erase
    Canvas->MoveTo(Origin.x, Origin.y);  // move pen to starting point
    Canvas->LineTo(MovePt.x, MovePt.y);  // erase old line
    Canvas->MoveTo(Origin.x, Origin.y);  // move pen to starting point again
    Canvas->LineTo(X, Y);                // draw new line
  }
  MovePt = Point(X, Y);      // record new endpoint
  Canvas->Pen->Mode = pmCopy;
}
```

Now you get a "rubber band" effect when you draw the line. By changing the pen's mode to *pmNotXor*, you have it combine your line with the background pixels. When you go to erase the line, you're actually setting the pixels back to the way they were. By changing the pen mode back to *pmCopy* (its default value) after drawing the lines, you ensure that the pen is ready to do its final

drawing when you release the mouse button.

See Also

Tracking the Origin Point (see page 2204)

3.2.4.13.51 Tracking the Origin Point

When drawing lines, track the point where the line starts with the *Origin* field. *Origin* must be set to the point where the mouse-down event occurs, so the mouse-up event handler can use *Origin* to place the beginning of the line, as in this code:

```
procedure TForm1.FormMouseDown(Sender: TObject; Button: TMouseButton;
Shift: TShiftState; X, Y: Integer);
begin
Drawing := True;
Canvas.MoveTo(X, Y);
Origin := Point(X, Y);{ record where the line starts }
end;
procedure TForm1.FormMouseUp(Sender: TObject; Button: TMouseButton;
Shift: TShiftState; X, Y: Integer);
begin
Canvas.MoveTo(Origin.X, Origin.Y);{ move pen to starting point }
Canvas.LineTo(X, Y);
Drawing := False;
end;
void __fastcall TForm1::FormMouseDown(TObject *Sender, TMouseButton Button,
  TShiftState Shift, int X, int Y)
{
  Drawing = true;            // set the Drawing flag
  Canvas->MoveTo(X, Y);      // set pen position
  Origin = Point(X, Y);      // record where the line starts
}
void __fastcall TForm1::FormMouseUp(TObject *Sender, TMouseButton Button,
  TShiftState Shift, int X, int Y)
{
  Canvas->MoveTo(Origin.x, Origin.y);  // move pen to starting point
  Canvas->LineTo(X, Y);                // draw line from PenPos to (X, Y)
  Drawing = false;                     // clear the Drawing flag
}
```

Those changes get the application to draw the final line again, but they do not draw any intermediate actions—the application does not yet support "rubber banding."

3.2.4.13.52 Types of Graphic Objects

The component library provides the following graphic objects. These objects have methods to draw on the canvas, which are described in Using Canvas methods to draw graphic objects (see page 2205) and to load and save to graphics files, as described in Loading and saving graphics files (see page 2194)

Graphic object types

Object	Description
Picture	Used to hold any graphic image. To add additional graphic file formats, use the Picture *Register* method. Use this to handle arbitrary files such as displaying images in an image control.
Bitmap	A powerful graphics object used to create, manipulate (scale, scroll, rotate, and paint), and store images as files on a disk. Creating copies of a bitmap is fast since the *handle* is copied, not the image.

Clipboard	Represents the container for any text or graphics that are cut, copied, or pasted from or to an application. With the clipboard, you can get and retrieve data according to the appropriate format; handle reference counting, and opening and closing the clipboard; manage and manipulate formats for objects in the clipboard.
Icon	Represents the value loaded from an icon file (::ICO file).
Metafile (VCL applications only)	Contains a file that records the operations required to construct an image, rather than contain the actual bitmap pixels of the image. Metafiles or drawings are extremely scalable without the loss of image detail and often require much less memory than bitmaps, particularly for high-resolution devices, such as printers. However, metafiles and drawings do not display as fast as bitmaps. Use a metafile or drawing when versatility or precision is more important than performance.

Common Properties and Methods of Canvas (see page 2184)

Refreshing the Screen (see page 2196)

3.2.4.13.53 Using Brushes

The Brush property of a canvas controls the way you fill areas, including the interior of shapes. Filling an area with a brush is a way of changing a large number of adjacent pixels in a specified way.

The brush has three properties you can manipulate:

- Color property changes the fill color.
- Style property changes the brush style.
- Bitmap property uses a bitmap as a brush pattern.

The values of these properties determine the way the canvas fills shapes or other areas. By default, every brush starts out white, with a solid style and no pattern bitmap.

You can use TBrushRecall for quick saving off and restoring the properties of brushes.

Using Pens (see page 2206)

Reading and Setting Pixels (see page 2196)

3.2.4.13.54 Using Canvas Methods to Draw Graphic Objects

This topic shows how to use some common methods to draw graphic objects. It covers:

- Drawing lines and polylines. (see page 2187)
- Drawing shapes. (see page 2190)
- Drawing rounded rectangles. (see page 2189)
- Drawing polygons. (see page 2189)

Drawing on a Bitmap (see page 2188)

Loading and Saving Graphics Files (see page 2194)

Using the Clipboard with Graphics (see page 2206)

Rubber Banding Example (see page 2199)

3.2.4.13.55 Using Drawing Tools

Now that you can tell what tool to use, you must indicate how to draw the different shapes. The only methods that perform any drawing are the mouse-move and mouse-up handlers, and the only drawing code draws lines, no matter what tool is selected.

To use different drawing tools, your code needs to specify how to draw, based on the selected tool. You add this instruction to each tool's event handler.

This topic describes:

- Drawing shapes (see page 2190).
- Sharing code among event handlers (see page 2202).

See Also

Keeping Track of Which Drawing Tool to Use (see page 2193)

Changing the Tool with Speed Buttons (see page 2184)

3.2.4.13.56 Using Pens

The Pen property of a canvas controls the way lines appear, including lines drawn as the outlines of shapes. Drawing a straight line is really just changing a group of pixels that lie between two points.

The pen itself has four properties you can change:

- Color property changes the pen color.
- Width property changes the pen width.
- Style property changes the pen style.
- Mode property changes the pen mode.

The values of these properties determine how the pen changes the pixels in the line. By default, every pen starts out black, with a width of 1 pixel, a solid style, and a mode called copy that overwrites anything already on the canvas.

You can use TPenRecall for quick saving off and restoring the properties of pens.

Using Brushes (see page 2205)

Reading and Setting Pixels (see page 2196)

3.2.4.13.57 Using the Clipboard with Graphics

You can use the Windows clipboard to copy and paste graphics within your applications or to exchange graphics with other applications. The VCL's clipboard object makes it easy to handle different kinds of information, including graphics.

Before you can use the clipboard object in your application, you must add the Clipbrd unit to the uses clause of any unit that needs to access clipboard data.

Loading and Saving Graphics Files (see page 2194)

Rubber Banding Example (see page 2199)

3.2.4.13.58 Using the Properties of the Canvas Object

With the Canvas object, you can set the properties of a pen for drawing lines, a brush for filling shapes, a font for writing text, and an array of pixels to represent the image.

This topic describes:

- Using pens (see page 2206).
- Using brushes (see page 2205).
- Reading and setting pixels (see page 2196).

3.2.4.13.59 What's in a Mouse Event

A mouse event occurs when a user moves the mouse in the user interface of an application. The VCL has three mouse events.

Mouse events

Event	Description
OnMouseDown event	Occurs when the user presses a mouse button with the mouse pointer over a control.
OnMouseMove event	Occurs when the user moves the mouse while the mouse pointer is over a control.
OnMouseUp event	Occurs when the user releases a mouse button that was pressed with the mouse pointer over a component.

When an application detects a mouse action, it calls whatever event handler you've defined for the corresponding event, passing five parameters. Use the information in those parameters to customize your responses to the events. The five parameters are as follows:

Mouse-event parameters

Parameter	Meaning
Sender	The object that detected the mouse action
Button	Indicates which mouse button was involved: *mbLeft, mbMiddle*, or *mbRight*
Shift	Indicates the state of the `Alt`, `Ctrl`, and `Shift` keys at the time of the mouse action
X, Y	The coordinates where the event occurred

Most of the time, you need the coordinates returned in a mouse-event handler, but sometimes you also need to check *Button* to determine which mouse button caused the event.

Note: Delphi uses the same criteria as Microsoft Windows in determining which mouse button has been pressed. Thus, if you have switched the default "primary" and "secondary" mouse buttons (so that the right mouse button is now the primary button), clicking the primary (right) button will record *mbLeft* as the value of the *Button* parameter.

3.2.4.13.60 Working with Graphics and Multimedia: Overview

Graphics and multimedia elements can add polish to your applications. You can introduce these features into your application in a variety of ways. To add graphical elements, you can insert pre-drawn pictures at design time, create them using graphical controls at design time, or draw them dynamically at runtime. To add multimedia capabilities, you can use special components that can play audio and video clips.

This following topics describe how to enhance your applications by introducing graphics or multimedia elements:

- Overview of Graphics Programming (see page 2176)
- Working with multimedia (see page 2177)

3.2.4.14 Working with packages and components

Topics

Name	Description
Loading Packages with the LoadPackage Function (see page 2211)	You can also load a package at runtime by calling the *LoadPackage* function. *LoadPackage* loads the package specified by its name parameter, checks for duplicate units, and calls the initialization blocks of all units contained in the package. For example, the following code could be executed when a file is chosen in a file-selection dialog.
Working with Packages and Components: Overview (see page 2211)	A *package* is a special dynamic-link library used by applications, the IDE, or both. *Runtime packages* provide functionality when a user runs an application. *Design-time* packages are used to install components in the IDE and to create special property editors for custom components. A single package can function at both design time and runtime, and design-time packages frequently work by calling runtime packages. To distinguish them from other DLLs, package libraries are stored in files that end with the .bpl (Borland package library) extension. Like other runtime libraries, packages contain code that can be shared among applications. For... more (see page 2211)
Compiling Packages (see page 2212)	You can compile a package from the IDE or from the command line.

Creating and Editing Packages (see page 2213)	Creating a package involves specifying: • A *name* for the package. • A list of other packages to be *required* by, or linked to, the new package. • A list of unit files to be *contained* by, or bound into, the package when it is compiled. The package is essentially a wrapper for these source-code units . The Contains clause is where you put the source-code units for custom components that you want to compile into a package. RAD Studio generates a package source file (.dpk). • Creating a Package (see page 2213) • Editing an Existing Package (see page 2216) • Editing Package Source Files Manually (see page 2216) • Understanding the Structure of a (see page 2220)... more (see page 2213)
Creating a Package (see page 2213)	Refer to Understanding the structure of a package (see page 2220) for more information about the steps outlined here.
Custom Packages (see page 2214)	A custom package is either a .bpl you code and compile yourself or an existing package from a third-party vendor. To use a custom runtime package with an application, choose **Project** ▶ **Options** and add the name of the package to the Runtime Packages edit box on the Packages page. For example, suppose you have a statistical package called stats.bpl. To use it in an application, the line you enter in the Runtime Packages edit box might look like this:
Deciding Which Runtime Packages to Use (see page 2214)	Several runtime packages, including rtl and vcl (VCL application) , supply basic language and component support. The vcl (VCL) package contains the most commonly used components; the rtl package includes all the non-component system functions and Windows interface elements. It does not include database or other special components, which are available in separate packages. To create a client/server database application that uses packages, you need several runtime packages, including vcl, vcldb, rtl, and dbrtl (VCL) . If you want to use visual components in your application, you also need vclx (VCL) . To use these packages, choose **Project** ▶ **Options**,... more (see page 2214)
Deploying Packages (see page 2215)	You deploy packages much like you deploy other applications. The files you distribute with a deployed package may vary. The bpl and any packages or dlls required by the bpl must be distributed. ***Files deployed with a package***
Design-time Packages (see page 2215)	Design-time packages are used to install components on the IDE's **Tool palette** and to create special property editors for custom components. Which ones are installed depends on which edition of Delphi you are using and whether or not you have customized it. You can view a list of what packages are installed on your system by choosing **Component** ▶ **Install Packages...**. The design-time packages work by calling runtime packages, which they reference in their Requires clause (see page 2220). For example, dclstd references vcl. The dclstd itself contains additional functionality that makes many of the standard components available on the **Tool palette... more (see page 2215)**
Editing an Existing Package (see page 2216)	
Editing Package Source Files Manually (see page 2216)	Package source files, like project files, are generated by Delphi from information you supply. Like project files, they can also be edited manually. A package source file should be saved with the .dpk (Delphi package) extension to avoid confusion with other files containing Del source code.
Installing Component Packages (see page 2217)	All components are installed in the IDE as packages. If you've written your own components, create and compile (see page 2213) a package that contains them. Your component source code must follow the model described in Overview of component creation. (see page 1313)

Package Collection Files (see page 2217)	Package collections (.dpc files) offer a convenient way to distribute packages to other developers. Each package collection contains one or more packages, including bpls and any additional files you want to distribute with them. When a package collection is selected for IDE installation, its constituent files are automatically extracted from their .pce container; the Installation dialog box offers a choice of installing all packages in the collection or installing packages selectively.
Package Files Created by Compiling (see page 2218)	To create a package, you compile a source file that has a .dpk extension. The base name of the .dpk file becomes the base name of the files generated by the compiler. For example, if you compile a package source file called traypak.dpk, the compiler creates a package called traypak.bpl.
Packages and Standard DLLs (see page 2219)	Create a package when you want to make a custom component that's available through the IDE. Create a standard DLL when you want to build a library that can be called from any application, regardless of the development tool used to build the application. The following table lists the file types associated with packages: ***Package files***
Package-specific Compiler Directives (see page 2219)	The following table lists package-specific compiler directives that you can insert into your source code. ***Package-specific compiler directives***
Runtime Packages (see page 2220)	Runtime packages are deployed with your applications. They provide functionality when a user runs the application. To run an application that uses packages, a computer must have both the application's executable file and all the packages (.bpl files) that the application uses. The .bpl files must be on the system path for an application to use them. When you deploy an application, you must make sure that users have correct versions of any required .bpls. • Loading packages in an application (see page 2221) • Deciding which runtime packages to use (see page 2214) • Custom packages (see page 2214)
Understanding the Structure of a Package (see page 2220)	Packages include the following parts: • Package name (see page 2220) • Requires clause (see page 2220) • Contains clause (see page 2220)
Loading Packages in an Application (see page 2221)	You can dynamically load packages by either: • Choosing Project Options dialog box in the IDE; or • Using the LoadPackage function (see page 2211).
Compiling and Linking from the Command Line (see page 2222)	When you compile from the command line, you can use the package-specific switches listed in the following table. ***Package-specific command-line compiler switches***
Weak Packaging (see page 2223)	The **$WEAKPACKAGEUNIT** directive affects the way a .dcu file is stored in a package's .dcp and .bpl files. (For information about files generated by the compiler, see Package files created when compiling (see page 2218).) If **{$WEAKPACKAGEUNIT ON}** appears in a unit file, the compiler omits the unit from bpls when possible, and creates a non-packaged local copy of the unit when it is required by another application or package. A unit compiled with this directive is said to be *weakly packaged*. For example, suppose you've created a package called pack1 that contains only one unit, unit1. Suppose unit1 does not... more (see page 2223)
Why Use Packages? (see page 2224)	Design-time packages simplify the tasks of distributing and installing custom components. Runtime packages, which are optional, offer several advantages over conventional programming. By compiling reused code into a runtime library, you can share it among applications. For example, all of your applications—including Delphi itself—can access standard components through packages. Since the applications don't have separate copies of the component library bound into their executables, the executables are much smaller, saving both system resources and hard disk storage. Moreover, packages allow faster compilation because only code unique to the application is compiled with each build.

3.2.4.14.1 Loading Packages with the LoadPackage Function

You can also load a package at runtime by calling the *LoadPackage* function. *LoadPackage* loads the package specified by its name parameter, checks for duplicate units, and calls the initialization blocks of all units contained in the package. For example, the following code could be executed when a file is chosen in a file-selection dialog.

```
with OpenDialog1 do
  if Execute then
    with PackageList.Items do
      AddObject(FileName, Pointer(LoadPackage(FileName)));
if (OpenDialog1->Execute())
  PackageList->Items->AddObject(OpenDialog1->FileName, (TObject
*)LoadPackage(OpenDialog1->FileName));
```

To unload a package dynamically, call *UnloadPackage*. Be careful to destroy any instances of classes defined in the package and to unregister classes that were registered by it.

Deploying Packages (see page 2215)

3.2.4.14.2 Working with Packages and Components: Overview

A *package* is a special dynamic-link library used by applications, the IDE, or both. *Runtime packages* provide functionality when a user runs an application. *Design-time* packages are used to install components in the IDE and to create special property editors for custom components. A single package can function at both design time and runtime, and design-time packages frequently work by calling runtime packages. To distinguish them from other DLLs, package libraries are stored in files that end with the .bpl (Borland package library) extension.

Like other runtime libraries, packages contain code that can be shared among applications. For example, the most frequently used VCL components reside in a package called vcl . Each time you create a new default VCL application, it automatically uses vcl. When you compile an application created this way, the application's executable image contains only the code and data unique to it; the common code is in the runtime package called vcl90.bpl. A computer with several package-enabled applications installed on it needs only a single copy of vcl90.bpl, which is shared by all the applications and the IDE itself.

Several runtime packages encapsulate VCL components while several design-time packages manipulate components in the IDE.

You can build applications with or without packages. However, if you want to add custom components to the IDE, you must install them as design-time packages.

You can create your own runtime packages to share among applications. If you write Delphi components, you can compile your components into design-time packages before installing them.

3.2.4.14.3 Compiling Packages

You can compile a package from the IDE or from the command line.

To recompile a package by itself from the IDE

1. Choose **File** ▸ **Open** and select a package (.dpk or .dpkw).
2. Click Open.
3. When the package opens:

- In the **Project Manager**, right-click the package and choose Compile.
- In the IDE, choose **Project** ▸ **Build**.

Note: Right-click the package project nodes for options to compile or build.

You can insert compiler directives into your package source code.

If you compile from the command line, you can use several package-specific switches.

- Package-specific Compiler Directives (see page 2219)
- Weak Packaging (see page 2223)
- Using the Command-line Compiler and Linker (see page 2222)
- Package Files Created by a Successful Compilation (see page 2218)

Working with Packages and Components: Overview (see page 2211)

Creating and Editing Packages (see page 2213)

3.2.4.14.4 Creating and Editing Packages

Creating a package involves specifying:

- A *name* for the package.
- A list of other packages to be *required* by, or linked to, the new package.
- A list of unit files to be *contained* by, or bound into, the package when it is compiled. The package is essentially a wrapper for these source-code units . The Contains clause is where you put the source-code units for custom components that you want to compile into a package.

RAD Studio generates a package source file (.dpk).

- Creating a Package (see page 2213)
- Editing an Existing Package (see page 2216)
- Editing Package Source Files Manually (see page 2216)
- Understanding the Structure of a Package (see page 2220)
- Compiling packages (see page 2212)

See Also

Working with Packages and Components: Overview (see page 2211)

3.2.4.14.5 Creating a Package

Refer to Understanding the structure of a package (see page 2220) for more information about the steps outlined here.

To create a package

1. Choose **File** ▸ **New** ▸ **Other**, select the Package icon under Delphi Projects, and click OK. The generated package appears in the **Project Manager**. The **Project Manager** displays a *Requires* node and a *Contains* node for the new package.
2. To add a unit to the **contains** clause, right-click the contains node in the **Project Manager** and select Add. In the Add Unit page, type a .pas file name in the Unit file name edit box, or click Browse to browse for the file, and then click OK. The unit you've selected appears under the Contains node in the **Project Manager**. You can add additional units by repeating this step.
3. To add a package to the **requires** clause, right-click the requires node in the **Project Manager** and select Add Reference. In the Requires page, type a .dcp file name in the Package name edit box, or click Browse to browse for the file, and then click OK. The package you've selected appears under the Requires node in the **Project Manager**. You can add additional packages by repeating this step.
4. In the **Project Manager**, right-click your package and select Compile.

Working with Packages and Components: Overview (see page 2211)

Creating and Editing Packages (see page 2213)

Editing an Existing Package (see page 2216)

3.2.4.14.6 Custom Packages

A custom package is either a .bpl you code and compile yourself or an existing package from a third-party vendor. To use a custom runtime package with an application, choose **Project** ▸ **Options** and add the name of the package to the Runtime Packages edit box on the Packages page.

For example, suppose you have a statistical package called stats.bpl. To use it in an application, the line you enter in the Runtime Packages edit box might look like this:

```
vcl;rtl;vcldb;stats //In VCL applications
```

If you create your own packages, add them to the list as needed.

See Also

Working with Packages and Components: Overview (see page 2211)

Runtime Packages (see page 2220)

Loading Packages in an Application (see page 2221)

3.2.4.14.7 Deciding Which Runtime Packages to Use

Several runtime packages, including rtl and vcl (VCL application) , supply basic language and component support. The vcl (VCL) package contains the most commonly used components; the rtl package includes all the non-component system functions and Windows interface elements. It does not include database or other special components, which are available in separate packages.

To create a client/server database application that uses packages, you need several runtime packages, including vcl, vcldb, rtl, and dbrtl (VCL) . If you want to use visual components in your application, you also need vclx (VCL) . To use these packages, choose **Project** ▸ **Options**, select the Packages tab, and make sure the following list is included in the Runtime Packages edit box. You need netclx for Web server applications, as well as baseclx and probably visualclx.

```
vcl;rtl;vcldb;vclx; //For VCL applications
```

Note: In VCL applications, you don't have to manually include vcl and rtl, because they are referenced in the Requires clause (see page 2220) of vcldb. Your application compiles just the same whether or not vcl and rtl are included in the Runtime Packages edit box.

Another way you can determine which packages are called by an application is to run it then review the event log (choose **View** ▸ **Debug Windows** ▸ **Event Log**). The event log displays every module that is loaded including all packages. The full package names are listed. So, for example, for vcl90.bpl , you would see a line similar to the following in a VCL application:

```
Module Load: vcl90.bpl Has Debug Info. Base Address $400B0000. Process Project1.exe ($22C)
```

Loading Packages in an Application (see page 2221)

Custom Packages (see page 2214)

3.2.4.14.8 Deploying Packages

You deploy packages much like you deploy other applications. The files you distribute with a deployed package may vary. The bpl and any packages or dlls required by the bpl must be distributed.

Files deployed with a package

File	Description
ComponentName.h	Allows end users access to the class interfaces.
ComponentName.cpp	Allows end users access to the component source.
.bpi, .obj, and .lib	Allows end users to link applications.

For general deployment information, refer to Deploying applications. (see page 1947)

Deploying applications that use packages

When distributing an application that uses runtime packages, make sure that your users have the application's .exe file as well as all the library (.bpl or .dll) files that the application calls. If the library files are in a different directory from the .exe file, they must be accessible through the user's Path. You may want to follow the convention of putting library files in the Windows\System directory. If you use InstallAware Express, your installation script can check the user's system for any packages it requires before blindly reinstalling them.

Distributing packages to other developers

If you distribute runtime or design-time packages to other Delphi developers, be sure to supply both .dcp and .bpl files. You will probably want to include .dcu files as well.

See Also

Working with Packages and Components: Overview (see page 2211)

3.2.4.14.9 Design-time Packages

Design-time packages are used to install components on the IDE's **Tool palette** and to create special property editors for custom components. Which ones are installed depends on which edition of Delphi you are using and whether or not you have customized it. You can view a list of what packages are installed on your system by choosing **Component ▸ Install Packages...**.

The design-time packages work by calling runtime packages, which they reference in their Requires clause (see page 2220). For example, dclstd references vcl. The dclstd itself contains additional functionality that makes many of the standard components available on the **Tool palette**.

In addition to preinstalled packages, you can install your own component packages, or component packages from third-party developers, in the IDE. The dclusr design-time package is provided as a default container for new components. See Installing Component Packages (see page 2217)

C++Builder supports compiling design-time packages that contain Delphi source files. However, if any of those Delphi sources make reference to IDE-supplied design-time units such as DesignIntf, DesignEditors, and ToolsAPI that exist in DesignIDE100.bpl, you must take steps to ensure that the references can be resolved by the C++Builder package. See Compiling C++ Design-Time Packages That Contain Delphi Source for details.

Runtime Packages (see page 2220)

Creating and Editing Packages (see page 2213)

Compiling C++ Design-Time Packages That Contain Delphi Source

3.2.4.14.10 Editing an Existing Package

To edit an existing package:

1. Choose **File** ▶ **Open** (or **File** ▶ **Reopen**) and select a dpk file.
2. In the Project Manager, select one of the packages in the Requires node, right-click, and choose Open.

The Project Options dialog has a Default check box in the lower left corner. If you click OK when this box is checked, the options you've chosen are saved as default settings for new projects. To restore the original defaults, delete or rename the defproj.dof file.

Working with Packages and Components: Overview (see page 2211)

Creating and Editing Packages (see page 2213)

Creating a Package (see page 2213)

Understanding the Structure of a Package (see page 2220)

Compiling Packages (see page 2212)

3.2.4.14.11 Editing Package Source Files Manually

Package source files, like project files, are generated by Delphi from information you supply. Like project files, they can also be edited manually. A package source file should be saved with the .dpk (Delphi package) extension to avoid confusion with other files containing Del source code.

To open a package source file in the Code editor

1. Open the package in RAD Studio.
2. Right-click the package in the **Project Manager** and choose View Source.

- The **package** heading specifies the name for the package.
- The **requires** clause lists other, external packages used by the current package. If a package does not contain any units that use units in another package, then it doesn't need a requires clause.
- The **contains** clause identifies the unit files to be compiled and bound into the package. All units used by contained units which do not exist in required packages will also be bound into the package, although they won't be listed in the contains clause (the compiler will give a warning). For example, the following VCL code declares the vcldb package (in the source file vcldb90.bpl):

```
package MyPack;
{$R *.res}
    ...{compiler directives omitted}
requires
    rtl,
    vcl;
contains
    Db,
    NewComponent1 in 'NewComponent1.pas';
end.
```

Understanding the Structure of a Package (see page 2220)

Compiling Packages (see page 2212)

3.2.4.14.12 Installing Component Packages

All components are installed in the IDE as packages. If you've written your own components, create and compile (see page 2213) a package that contains them. Your component source code must follow the model described in Overview of component creation. (see page 1313)

To install or uninstall your own components, or components from a third-party vendor

1. If you are installing a new package, copy or move the package files to a local directory. If the package is shipped with .bpl (see page 2219), be sure to copy all of them. The directory where you store the .dcp file—and the .dcu files, if they are included with the distribution—must be in the Delphi Library Path.
2. Choose **Component ▸ Install Packages** from the IDE menu, or choose **Project ▸ Options** and click the Packages tab. A list of available packages appears in the Design packages list box.

- To install a package in the IDE, select the check box next to it.
- To uninstall a package, uncheck its check box.
- To see a list of components included in an installed package, select the package and click Components.
- To add a package to the list, click Add and browse in the Add Design Package dialog for the directory where the .bpl file resides (see step 1). Select the .bpl or .dpc file and click Open. If you select a .dpc file, a new dialog box appears to handle the extraction of the .bpl and other files from the package collection.
- To remove a package from the list, select the package and click Remove.

3. Click OK.

The components in the package are installed on the **Tool palette** pages specified in the components' *RegisterComponents* procedure, with the names they were assigned in the same procedure.

New projects are created with all available packages installed, unless you change the ddefault settings. To make the current installation choices into the automatic default for new projects, check the Default check box at the bottom of the Packages tab of the Project Options dialog box.

To remove components from the **Tool palette** without uninstalling a package, right-click the component to invoke the context menu and choose Hide "<ComponentName>" Button.

Working with Packages and Components: Overview (see page 2211)

Design-time Packages (see page 2215)

3.2.4.14.13 Package Collection Files

Package collections (.dpc files) offer a convenient way to distribute packages to other developers. Each package collection contains one or more packages, including bpls and any additional files you want to distribute with them. When a package collection is selected for IDE installation, its constituent files are automatically extracted from their .pce container; the Installation dialog box offers a choice of installing all packages in the collection or installing packages selectively.

To create package collection files

1. Choose **Tools ▸ Package Collection Editor** to open the Package Collection editor.
2. Either choose **Edit ▸ Add Package** or click the Add a package button, then select a bpl in the Select Package dialog and click Open. To add more bpls to the collection, click the Add a package button again. A tree diagram on the left side of the Package editor displays the bpls as you add them. To remove a package, select it and either choose **Edit ▸ Remove Package** or click

the Remove the selected package button.

3. Select the Collection node at the top of the tree diagram. On the right side of the Package Collection editor, two fields appear:

- In the Author/Vendor Name edit box, you can enter optional information about your package collection that appear in the Installation dialog when users install packages.
- Under Directory list, list the default directories where you want the files in your package collection to be installed. Use the Add, Edit, and Delete buttons to edit this list. For example, suppose you want all source code files to be copied to the same directory. In this case, you might enter Source as a Directory name with C:\MyPackage\Source as the Suggested path. The Installation dialog box will display C:\MyPackage\Source as the suggested path for the directory.

4. In addition to bpls, your package collection can contain .dcp, .dcu, and .pas (unit) files, documentation, and any other files you want to include with the distribution. Ancillary files are placed in file groups associated with specific packages (bpls); the files in a group are installed only when their associated bpl is installed. To place ancillary files in your package collection, select a bpl in the tree diagram and click the Add a file group button; type a name for the file group. Add more file groups, if desired, in the same way. When you select a file group, new fields will appear on the right in the Package Collection editor.

- In the Install Directory list box, select the directory where you want files in this group to be installed. The drop-down list includes the directories you entered under Directory list in step 3, above.
- Check the Optional Group check box if you want installation of the files in this group to be optional.
- Under Include Files, list the files you want to include in this group. Use the Add, Delete, and Auto buttons to edit the list. The Auto button allows you to select all files with specified extensions that are listed in the **contains** clause of the package; the Package Collection editor uses the global Library Path to search for these files.

5. You can select installation directories for the packages listed in the **requires** clause of any package in your collection. When you select a bpl in the tree diagram, four new fields appear on the right side of the Package Collection editor:

- In the Required Executables list box, select the directory where you want the .bpl files for packages listed in the **requires** clause to be installed. (The drop-down list includes the directories you entered under Directory list in step 3, above.) The Package Collection editor searches for these files using Delphi's global Library Path and lists them under Required Executable Files.
- In the Required Libraries list box, select the directory where you want the .dcp files for packages listed in the **requires** clause to be installed. (The drop-down list includes the directories you entered under Directory List in step 3, above.) The Package Collection editor searches for these files using the global Library Path and lists them under Required Library Files.

6. To save your package collection source file, choose **File ▸ Save**. Package collection source files should be saved with the .pce extension.

7. To build your package collection, click the Compile button. The Package Collection editor generates a .dpc file with the same name as your source (.pce) file. If you have not yet saved the source file, the editor queries you for a file name before compiling.

To edit or recompile an existing .pce file, select **File ▸ Open** in the Package Collection editor and locate the file you want to work with.

See Also

Working with Packages and Components: Overview (see page 2211)

3.2.4.14.14 Package Files Created by Compiling

To create a package, you compile a source file that has a .dpk extension. The base name of the .dpk file becomes the base name of the files generated by the compiler. For example, if you compile a package source file called traypak.dpk, the compiler creates a package called traypak.bpl.

```
<PROJECT value="Traypak.bpl"/>
```

A successfully compiled package includes .dcp, .dcu and bpl files. For a detailed description of these files, see Packages and standard DLLs (see page 2219).

These files are generated by default in the directories specified in Library page of the **Tools ▸ Options ▸ Environment Options ▸ Delphi Options ▸ Library** dialog. You can override the default settings by right-clicking the package in the **Project**

Manager and choosing Options to display the Project Options dialog; make any changes on the Directories/Conditionals page.

Working with Packages and Components: Overview (see page 2211)

Compiling Packages (see page 2212)

Compiling and Linking from the Command Line (see page 2222)

3.2.4.14.15 Packages and Standard DLLs

Create a package when you want to make a custom component that's available through the IDE. Create a standard DLL when you want to build a library that can be called from any application, regardless of the development tool used to build the application.

The following table lists the file types associated with packages:

Package files

File extension	Contents
.bpf	A source file required for a package.
bpi	A Borland package import library. A .bpi is created for each package. The bpis for bpls is analogous to import libraries for dlls. This file is passed to the linker by applications using the package to resolve references to functions in the package. The base name for the bpi is the base name for the package source file.
bpk and bpkw	The project options source file. This file is the XML portion of the package project. The ProjectName.bpk and ProjectName.cpp combined are used to manage settings, options, and files used by the package project. .bpk and .bpkw packages are identical, but use the .bpkw extension for packages that you want to use in cross-platform applications.
bpl	The runtime package. This file is a Windows .dll with special -specific features. The base name for the .bpl is the base name of the .bpk or .bpkw source file.
cpp	ProjectName.cpp contains the entry point for the package. Additionally, each component contained within the package generally resides within a .cpp file.
h	The header file or interface for the component. C omponentN ame.h is the companion to C omponentN ame.cpp.
lib	A static library, or collection of .objs , used in place of a .bpi when the application does not use runtime packages. Generated only if the **-Gl** (Generate .lib file) linker option is selected.
obj	A binary image for a unit file contained in a package. One .obj is created, when necessary, for each .cpp file.

Note: Packages share their global data with other modules in an application.

Working with Packages and Components: Overview (see page 2211)

Overview of Component Creation (see page 1313)

3.2.4.14.16 Package-specific Compiler Directives

The following table lists package-specific compiler directives that you can insert into your source code.

Package-specific compiler directives

Directive	Purpose
#pragma package(smart_init)	Assures that packaged units are initialized in the order determined by their dependencies. (Included by default in package source file.)
#pragma package(smart_init, weak)	Packages unit "weakly." See (Put directive in unit source file.)

Note: Including **{$DENYPACKAGEUNIT ON}** in your source code prevents the unit file from being packaged. Including **{$G-}** or **{$IMPORTEDDATA OFF}** may prevent a package from being used in the same application with other packages. Packages compiled with the **{$DESIGNONLY ON}** directive should not ordinarily be used in applications, since they contain extra code required by the IDE. Other compiler directives may be included, if appropriate, in package source code. See Compiler Directives for information on compiler directives not discussed here.

See Package-specific Compiler Directives.

Refer to Creating Packages and DLLs (see page 1882) for additional directives that can be used in all libraries.

Working with Packages and Components: Overview (see page 2211)

Compiling Packages (see page 2212)

Creating and Editing Packages (see page 2213)

3.2.4.14.17 Runtime Packages

Runtime packages are deployed with your applications. They provide functionality when a user runs the application.

To run an application that uses packages, a computer must have both the application's executable file and all the packages (.bpl files) that the application uses. The .bpl files must be on the system path for an application to use them. When you deploy an application, you must make sure that users have correct versions of any required .bpls.

- Loading packages in an application (see page 2221)
- Deciding which runtime packages to use (see page 2214)
- Custom packages (see page 2214)

See Also

Working with Packages and Components: Overview (see page 2211)

3.2.4.14.18 Understanding the Structure of a Package

Packages include the following parts:

- Package name
- Requires clause
- Contains clause

Naming packages

Package names must be unique within a project. If you name a package Stats, RAD Studio generates a source file for it called Stats.dpk; the compiler generates an executable and a binary image called Stats.bpl and Stats.dcp, respectively. Use Stats to refer to the package in the **requires** clause of another package, or when using the package in an application.

Requires clause

The **requires** clause specifies other, external packages that are used by the current package. An external package included in

the **requires** clause is automatically linked at compile time into any application that uses both the current package and one of the units contained in the external package.

If the unit files contained in your package make references to other packaged units, the other packages should appear in your package's **requires** clause or you should add them. If the other packages are omitted from the **requires** clause, the compiler will import them into your package 'implicitly contained units.'

Note: Most packages that you create require rtl. If using VCL components, you'll also need to include the vcl package.

Avoiding circular package references

Packages cannot contain circular references in their requires clause. This means that:

- A package cannot reference itself in its own **requires** clause.
- A chain of references must terminate without rereferencing any package in the chain. If package A requires package B, then package B cannot require package A; if package A requires package B and package B requires package C, then package C cannot require package A.

Handling duplicate package references

Duplicate references in a package's **requires** clause—or the Runtime Packages edit box—are ignored by the compiler. For programming clarity and readability, however, you should catch and remove duplicate package references.

Contains clause

The **contains** clause identifies the unit files to be bound into the package. If you are writing your own package, put your source code in pas files and include them in the **contains** clause.

Avoiding redundant source code uses

A package cannot appear in the containsclause of another package.

All units included directly in a package's **contains** clause, or included indirectly in any of those units, are bound into the package at compile time.

A unit cannot be contained (directly or indirectly) in more than one package used by the same application, including the IDE. This means that if you create a package that contains one of the units in vcl (VCL) you won't be able to install your package in the IDE. To use an already-packaged unit file in another package, put the first package in the second package's **requires** clause.

See Also

Working with Packages and Components: Overview (see page 2211)

Creating and Editing Packages (see page 2213)

3.2.4.14.19 Loading Packages in an Application

You can dynamically load packages by either:

- Choosing Project Options dialog box in the IDE; or
- Using the LoadPackage function (see page 2211).

To load packages using the >Project>Options dialog box

1. Load or create a project in the IDE.
2. Choose **Project** ▸ **Options**.
3. Choose the Packages tab.
4. Select the Build with Runtime Packages check box, and enter one or more package names in the edit box underneath. Each package is loaded implicitly only when it is needed (that is, when you refer to an object defined in one of the units in that package). (Runtime packages associated with installed design-time packages are already listed in the edit box.)

5. To add a package to an existing list, click the Add button and enter the name of the new package in the Add Runtime Package dialog. To browse from a list of available packages, click the Add button, then click the Browse button next to the Package Name edit box in the Add Runtime Package dialog. If you edit the Search Path edit box in the Add Runtime Package dialog, you can change the global Library Path. You do not need to include file extensions with package names (or the version number representing the Delphi release); that is, vcl90.bpl in a VCL application is written as vcl. If you type directly into the Runtime Package edit box, be sure to separate multiple names with semicolons. For example:

```
rtl;vcl;vcldb;vclado;

vclbde;
```

Packages listed in the Runtime Packages edit box are automatically linked to your application when you compile. Duplicate package names are ignored, and if the Build with runtime packages check box is unchecked, the application is compiled without packages. Runtime packages are selected for the current project only. To make the current choices into automatic defaults for new projects, select the Defaults check box at the bottom of the dialog.

Note: When you create an application with packages, you must include the names of the original Delphi units in the **uses** clause of your source files. For example, the source file for your main form might begin like this:

```
unit MainForm;
interface
uses

#include "vcldb.h"
```

The units referenced in this VCL example are contained in the vcl and rtl packages. Nonetheless, you must keep these references in the **uses** clause, even if you use vcl and rtl in your application, or you will get compiler errors. In generated source files, the Form Designer adds these units to the uses clause automatically.

Loading Packages with the LoadPackage Function (see page 2211)

3.2.4.14.20 Compiling and Linking from the Command Line

When you compile from the command line, you can use the package-specific switches listed in the following table.

Package-specific command-line compiler switches

Switch	Purpose
$G	Disables creation of imported data references. Using this switch increases memory-access efficiency, but prevents packages compiled with it from referencing variables in other packages.
-LE*path*	Specifies the directory where the package file (.bpl) will be placed.
-LN*path*	Specifies the directory where the package file (.dcp) will be placed.
-LUpackage	Use packages.
-Z	Prevents a package from being implicitly recompiled later. Use when compiling packages that provide low-level functionality, that change infrequently between builds, or whose source code will not be distributed.

Note: Using the **-$G-** switch may prevent a package from being used in the same application with other packages. Other

command-line options may be used, if appropriate, when compiling packages. See The Command-line Compiler for information on command-line options not discussed here.

Package-specific command-line compiler and linker switches

Switch	Purpose
tP	Generates a project as a package (compiler switch).
-D "*description*"	Saves the specified description with the package.
-Gb	Generates the .bpl filename.
-Gi	Saves the generated .bpi file. Included by default in package project files.
-Gpd	Generates a design-time-only package.
-Gpr	Generates a runtime-only package.
-Gl	Generates a .lib file.
-Tpp	Builds the project as a package. Included by default in package project files.

Compiling Packages (see page 2212)

3.2.4.14.21 Weak Packaging

The **$WEAKPACKAGEUNIT** directive affects the way a .dcu file is stored in a package's .dcp and .bpl files. (For information about files generated by the compiler, see Package files created when compiling (see page 2218).) If **{$WEAKPACKAGEUNIT ON}** appears in a unit file, the compiler omits the unit from bpls when possible, and creates a non-packaged local copy of the unit when it is required by another application or package. A unit compiled with this directive is said to be *weakly packaged*.

For example, suppose you've created a package called pack1 that contains only one unit, unit1. Suppose unit1 does not use any additional units, but it makes calls to rare.dll. If you put the **{$WEAKPACKAGEUNIT ON}** directive in unit1.pas (Delphi) or unit1.cpp (C++) when you compile your package, unit1 will not be included in pack1.bpl; you will not have to distribute copies of rare.dll with pack1. However, unit1 will still be included in pack1.dcp. If unit1 is referenced by another package or application that uses pack1, it will be copied from pack1.dcp and compiled directly into the project.

Now suppose you add a second unit, unit2, to pack1. Suppose that unit2 uses unit1. This time, even if you compile pack1 with **{$WEAKPACKAGEUNIT ON}** in unit1.pas, the compiler will include unit1 in pack1.bpl. But other packages or applications that reference unit1 will use the (non-packaged) copy taken from pack1.dcp.

Note: Unit files containing the **{$WEAKPACKAGEUNIT ON}** directive must not have global variables, initialization sections, or finalization sections.

The **{$WEAKPACKAGEUNIT ON}** directive is an advanced feature intended for developers who distribute their packages to other programmers. It can help you to avoid distribution of infrequently used DLLs, and to eliminate conflicts among packages that may depend on the same external library.

For example, the PenWin unit references PenWin.dll. Most projects don't use PenWin, and most computers don't have PenWin.dll installed on them. For this reason, the PenWin unit is weakly packaged in vcl. When you compile a project that uses PenWin and the vcl package, PenWin is copied from vcl70.dcp and bound directly into your project; the resulting executable is statically linked to PenWin.dll.

If PenWin were not weakly packaged, two problems would arise. First, vcl itself would be statically linked to PenWin.dll, and so you could not load it on any computer which didn't have PenWin.dll installed. Second, if you tried to create a package that contained PenWin, a compiler error would result because the PenWin unit would be contained in both vcl and your package. Thus, without weak packaging, PenWin could not be included in standard distributions of vcl.

3.2.4.14.22 Why Use Packages?

Design-time packages simplify the tasks of distributing and installing custom components. Runtime packages, which are optional, offer several advantages over conventional programming. By compiling reused code into a runtime library, you can share it among applications. For example, all of your applications—including Delphi itself—can access standard components through packages. Since the applications don't have separate copies of the component library bound into their executables, the executables are much smaller, saving both system resources and hard disk storage. Moreover, packages allow faster compilation because only code unique to the application is compiled with each build.

3.2.4.15 Writing multi-threaded applications

Topics

Name	Description
Coordinating threads (see page 2225)	
Writing Multi-threaded Applications (see page 2231)	Several objects make writing multi-threaded applications easier. Multi-threaded applications are applications that include several simultaneous paths of execution. While using multiple threads requires careful thought, it can enhance your programs by: • **Avoiding bottlenecks.** With only one thread, a program must stop all execution when waiting for slow processes such as accessing files on disk, communicating with other machines, or displaying multimedia content. The CPU sits idle until the process completes. With multiple threads, your application can continue execution in separate threads while one thread waits for the results of a slow process. • **Organizing program behavior.** Often, a program's behavior can... more (see page 2231)
Defining thread objects (see page 2231)	
Executing thread objects (see page 2238)	

3.2.4.15.1 Coordinating threads

Topics

Name	Description
Other Techniques for Sharing Memory (see page 2226)	When using VCL objects, use the main thread to execute your code. Using the main thread ensures that the object does not indirectly access any memory that is also used by VCL objects in other threads. See Using the Main VCL Thread (see page 2235) for more information on the main thread. If the global memory does not need to be shared by multiple threads, consider using thread-local variables instead of global variables. By using thread-local variables, your thread does not need to wait for or lock out any other threads. See Using Thread-local Variables (see page 2237) for more information about thread-local variables.
Avoiding Simultaneous Access (see page 2226)	To avoid clashing with other threads when accessing global objects or variables, you may need to block the execution of other threads until your thread code has finished an operation. Be careful not to block other execution threads unnecessarily. Doing so can cause performance to degrade seriously and negate most of the advantages of using multiple threads. Three techniques prevent other threads from accessing the same memory as your thread: • Locking Objects (see page 2227) • Using Critical Sections (see page 2227) • Using a Multi-read Exclusive-write Synchronizer (see page 2228)
Coordinating Threads (see page 2227)	When writing the code that runs when your thread is executed, you must consider the behavior of other threads that may be executing simultaneously. In particular, care must be taken to avoid two threads trying to use the same global object or variable at the same time. In addition, the code in one thread can depend on the results of tasks performed by other threads. Whether using thread objects or generating threads using *BeginThread*, the following topics describe techniques for coordinating threads: • Avoiding Simultaneous Access (see page 2226) • Waiting for Other Threads (see page 2230) • Using the Main VCL Thread (see page 2235) When global memory does not... more (see page 2227)
Locking Objects (see page 2227)	Some objects have built-in locking that prevents the execution of other threads from using that object instance. For example, canvas objects (*TCanvas* and descendants) have a Lock method that prevents other threads from accessing the canvas until the Unlock method is called. VCL applications also include a thread-safe list object, TThreadList. Calling LockList returns the list object while also blocking other execution threads from using the list until the UnlockList method is called. Calls to *TCanvas.Lock* or *TThreadList.LockList* can be safely nested. The lock is not released until the last locking call is matched with a corresponding unlock call... more (see page 2227)
Using Critical Sections (see page 2227)	If objects do not provide built-in locking, you can use a critical section. Critical sections work like gates that allow only a single thread to enter at a time. To use a critical section, create a global instance of TCriticalSection. *TCriticalSection* has two methods, Acquire*(which blocks other threads from executing the section)* and Release*(which removes the block).* *Each critical section is associated with the global memory you want to protect. Every thread that accesses that global memory should first use the Acquire method to ensure that no other thread is using it. When finished, threads call the Release... more (see page 2227)*

Using the Multi-read Exclusive-write Synchronizer (see page 2228)	When you use critical sections to protect global memory, only one thread can use the memory at a time. This can be more protection than you need, especially if you have an object or variable that must be read often but to which you very seldom write. There is no danger in multiple threads reading the same memory simultaneously, as long as no thread is writing to it. When you have some global memory that is read often, but to which threads occasionally write, you can protect it using TMultiReadExclusiveWriteSynchronizer. This object acts like a critical section, but allows multiple... more (see page 2228)
Waiting for a Task to Be Completed (see page 2229)	Sometimes, you need to wait for a thread to finish some operation rather than waiting for a particular thread to complete execution. To do this, use an event object. Event objects (TEvent) should be created with global scope so that they can act like signals that are visible to all threads. When a thread completes an operation that other threads depend on, it calls *TEvent.SetEvent*. SetEvent turns on the signal, so any other thread that checks will know that the operation has completed. To turn off the signal, use the ResetEvent method. For example, consider a situation where you... more (see page 2229)
Waiting for a Thread to Finish Executing (see page 2230)	To wait for another thread to finish executing, use the WaitFor method of that other thread. *WaitFor* doesn't return until the other thread terminates, either by finishing its own Execute method or by terminating due to an exception. For example, the following code waits until another thread fills a thread list object before accessing the objects in the list:
Waiting for Other Threads (see page 2230)	If your thread must wait for another thread to finish some task, you can tell your thread to temporarily suspend execution. You can either • Wait for another thread to completely finish executing (see page 2230), or • Wait for a task to be completed (see page 2229).

3.2.4.15.1.1 Other Techniques for Sharing Memory

When using VCL objects, use the main thread to execute your code. Using the main thread ensures that the object does not indirectly access any memory that is also used by VCL objects in other threads. See Using the Main VCL Thread (see page 2235) for more information on the main thread.

If the global memory does not need to be shared by multiple threads, consider using thread-local variables instead of global variables. By using thread-local variables, your thread does not need to wait for or lock out any other threads. See Using Thread-local Variables (see page 2237) for more information about thread-local variables.

Using Critical Sections (see page 2227)

Using the Multi-read Exclusive-write Synchronizer (see page 2228)

3.2.4.15.1.2 Avoiding Simultaneous Access

To avoid clashing with other threads when accessing global objects or variables, you may need to block the execution of other threads until your thread code has finished an operation. Be careful not to block other execution threads unnecessarily. Doing so can cause performance to degrade seriously and negate most of the advantages of using multiple threads.

Three techniques prevent other threads from accessing the same memory as your thread:

- Locking Objects (see page 2227)
- Using Critical Sections (see page 2227)
- Using a Multi-read Exclusive-write Synchronizer (see page 2228)

See Also

Using the Main VCL Thread (see page 2235)

Using Thread-local Variables (see page 2237)

Waiting for Other Threads (see page 2230)

3.2.4.15.1.3 Coordinating Threads

When writing the code that runs when your thread is executed, you must consider the behavior of other threads that may be executing simultaneously. In particular, care must be taken to avoid two threads trying to use the same global object or variable at the same time. In addition, the code in one thread can depend on the results of tasks performed by other threads.

Whether using thread objects or generating threads using *BeginThread*, the following topics describe techniques for coordinating threads:

- Avoiding Simultaneous Access (see page 2226)
- Waiting for Other Threads (see page 2230)
- Using the Main VCL Thread (see page 2235)

When global memory does not need to be shared by multiple threads, consider using thread-local variables (see page 2237) instead of global variables. By using thread-local variables, your thread does not need to wait for or lock out any other threads.

See Also

Executing Thread Objects (see page 2242)

Defining Thread Objects (see page 2233)

3.2.4.15.1.4 Locking Objects

Some objects have built-in locking that prevents the execution of other threads from using that object instance.

For example, canvas objects (*TCanvas* and descendants) have a Lock method that prevents other threads from accessing the canvas until the Unlock method is called.

VCL applications also include a thread-safe list object, TThreadList. Calling LockList returns the list object while also blocking other execution threads from using the list until the UnlockList method is called. Calls to *TCanvas.Lock* or *TThreadList.LockList* can be safely nested. The lock is not released until the last locking call is matched with a corresponding unlock call in the same thread.

Using Critical Sections (see page 2227)

Using the Main VCL Thread (see page 2235)

Using the Multi-read Exclusive-write Synchronizer (see page 2228)

3.2.4.15.1.5 Using Critical Sections

If objects do not provide built-in locking, you can use a critical section. Critical sections work like gates that allow only a single thread to enter at a time. To use a critical section, create a global instance of TCriticalSection. *TCriticalSection* has two methods, Acquire*(which blocks other threads from executing the section) and Release(which removes the block).*

Each critical section is associated with the global memory you want to protect. Every thread that accesses that global memory should first use the Acquire method to ensure that no other thread is using it. When finished, threads call the Release method so that other threads can access the global memory by calling Acquire.

Warning: *Critical sections only work if every thread uses them to access the associated global memory. Threads that ignore the critical section and access the global memory without calling Acquire can introduce problems of simultaneous access.*

For example, consider an application that has a global critical section variable, LockXY, that blocks access to global variables X and Y. Any thread that uses X or Y must surround that use with calls to the critical section such as the following:

```
LockXY.Acquire; { lock out other threads }
try
Y := sin(X);
finally
LockXY.Release;
end;
```

```
pLockXY->Acquire(); // lock out other threads
try
{
Y = sin(X);
}
__finally
{
pLockXY->Release();
}
```

Locking Objects (see page 2227)

Using the Main VCL Thread (see page 2235)

Using the Multi-read Exclusive-write Synchronizer (see page 2228)

3.2.4.15.1.6 Using the Multi-read Exclusive-write Synchronizer

When you use critical sections to protect global memory, only one thread can use the memory at a time. This can be more protection than you need, especially if you have an object or variable that must be read often but to which you very seldom write. There is no danger in multiple threads reading the same memory simultaneously, as long as no thread is writing to it.

When you have some global memory that is read often, but to which threads occasionally write, you can protect it using TMultiReadExclusiveWriteSynchronizer. This object acts like a critical section, but allows multiple threads to read the memory it protects as long as no thread is writing to it. Threads must have exclusive access to write to memory protected by *TMultiReadExclusiveWriteSynchronizer*.

To use a multi-read exclusive-write synchronizer, create a global instance of *TMultiReadExclusiveWriteSynchronizer* that is associated with the global memory you want to protect. Every thread that reads from this memory must first call the BeginRead method. *BeginRead* ensures that no other thread is currently writing to the memory. When a thread finishes reading the protected memory, it calls the EndRead method. Any thread that writes to the protected memory must call BeginWrite first. *BeginWrite* ensures that no other thread is currently reading or writing to the memory. When a thread finishes writing to the protected memory, it calls the EndWrite method, so that threads waiting to read the memory can begin.

Warning: Like critical sections, the multi-read exclusive-write synchronizer only works if every thread uses it to access the associated global memory. Threads that ignore the synchronizer and access the global memory without calling *BeginRead* or *BeginWrite* introduce problems of simultaneous access.

Locking Objects (see page 2227)

Using the Main VCL Thread (see page 2235)

Using Critical Sections (see page 2227)

3.2.4.15.1.7 Waiting for a Task to Be Completed

Sometimes, you need to wait for a thread to finish some operation rather than waiting for a particular thread to complete execution. To do this, use an event object. Event objects (TEvent) should be created with global scope so that they can act like signals that are visible to all threads.

When a thread completes an operation that other threads depend on, it calls *TEvent.SetEvent*. SetEvent turns on the signal, so any other thread that checks will know that the operation has completed. To turn off the signal, use the ResetEvent method.

For example, consider a situation where you must wait for several threads to complete their execution rather than a single thread. Because you don't know which thread will finish last, you can't simply use the WaitFor method of one of the threads. Instead, you can have each thread increment a counter when it is finished, and have the last thread signal that they are all done by setting an event.

The following code shows the end of the OnTerminate event handler for all of the threads that must complete. *CounterGuard* is a global critical section object that prevents multiple threads from using the counter at the same time. *Counter* is a global variable that counts the number of threads that have completed.

```
procedure TDataModule.TaskThreadTerminate(Sender: TObject);
begin
...
CounterGuard.Acquire; { obtain a lock on the counter }
Dec(Counter);   { decrement the global counter variable }
if Counter = 0 then
Event1.SetEvent; { signal if this is the last thread }
CounterGuard.Release; { release the lock on the counter }
...
end;
void __fastcall TDataModule::TaskThreadTerminate(TObject *Sender)
{
...
CounterGuard->Acquire(); // lock the counter
if (--Counter == 0)    // decrement the global counter
Event1->SetEvent(); // signal if this is the last thread
CounterGuard->Release(); // release the lock on the counter
}
```

The main thread initializes the Counter variable, launches the task threads, and waits for the signal that they are all done by calling the WaitFor method. *WaitFor* waits for a specified time period for the signal to be set, and returns one of the values from the following table:

WaitFor return values

Value	Meaning
wrSignaled	The signal of the event was set.
wrTimeout	The specified time elapsed without the signal being set.
wrAbandoned	The event object was destroyed before the time-out period elapsed.
wrError	An error occurred while waiting.

The following shows how the main thread launches the task threads and then resumes when they have all completed:

```
Event1.ResetEvent; { clear the event before launching the threads }
for i := 1 to Counter do
TaskThread.Create(False); { create and launch task threads }
if Event1.WaitFor(20000) <> wrSignaled then
raise Exception;
{ now continue with the main thread. All task threads have finished }
Event1->ResetEvent(); // clear the event before launching the threads
for (int i = 0; i < Counter; i++)
```

```
new TaskThread(false); // create and launch task threads
if (Event1->WaitFor(20000) != wrSignaled)
throw Exception;
// now continue with the main thread, all task threads have finished
```

Note: If you do not want to stop waiting for an event after a specified time period, pass the *WaitFor* method a parameter value of INFINITE. Be careful when using INFINITE, because your thread will hang if the anticipated signal is never received.

See Also

Waiting for a Thread to Finish Executing (see page 2230)

Using the Main VCL Thread (see page 2235)

3.2.4.15.1.8 Waiting for a Thread to Finish Executing

To wait for another thread to finish executing, use the WaitFor method of that other thread. *WaitFor* doesn't return until the other thread terminates, either by finishing its own Execute method or by terminating due to an exception. For example, the following code waits until another thread fills a thread list object before accessing the objects in the list:

```
if ListFillingThread.WaitFor then
begin
with ThreadList1.LockList do
begin
for I := 0 to Count - 1 do
ProcessItem(Items[I]);
end;
ThreadList1.UnlockList;
end;
if (pListFillingThread->WaitFor())
{
  TList *pList = ThreadList1->LockList();
for (int i = 0; i < pList->Count; i++)
ProcessItem(pList->Items[i]);
ThreadList1->UnlockList();
}
```

In the previous example, the list items were only accessed when the *WaitFor* method indicated that the list was successfully filled. This return value must be assigned by the *Execute* method of the thread that was waited for. However, because threads that call *WaitFor* want to know the result of thread execution, not code that calls *Execute*, the *Execute* method does not return any value. Instead, the *Execute* method sets the ReturnValue property. *ReturnValue* is then returned by the *WaitFor* method when it is called by other threads. Return values are integers. Your application determines their meaning.

Using the Main VCL Thread (see page 2235)

Using Thread-local Variables (see page 2237)

3.2.4.15.2 Writing Multi-threaded Applications

Several objects make writing multi-threaded applications easier. Multi-threaded applications are applications that include several simultaneous paths of execution. While using multiple threads requires careful thought, it can enhance your programs by:

- **Avoiding bottlenecks.** With only one thread, a program must stop all execution when waiting for slow processes such as accessing files on disk, communicating with other machines, or displaying multimedia content. The CPU sits idle until the process completes. With multiple threads, your application can continue execution in separate threads while one thread waits for the results of a slow process.
- **Organizing program behavior.** Often, a program's behavior can be organized into several parallel processes that function independently. Use threads to launch a single section of code simultaneously for each of these parallel cases. Use threads to assign priorities to various program tasks so that you can give more CPU time to more critical tasks.
- **Multiprocessing.** If the system running your program has multiple processors, you can improve performance by dividing the work into several threads and letting them run simultaneously on separate processors.

  Note: Not all operating systems implement true multi-processing, even when it is supported by the underlying hardware. For example, Windows 9x only simulates multiprocessing, even if the underlying hardware supports it.

  The following topics discuss support for threads:

- Defining Thread Objects (see page 2233)
- Coordinating Threads (see page 2227)
- Executing Thread Objects (see page 2242)
- Debugging Multi-threaded Applications (see page 2241)

Blocking Connections (see page 2340)

Managing Multiple Sessions (see page 1659)

3.2.4.15.3 Defining thread objects

Topics

Name	Description
Checking for Termination by Other Threads (see page 2232)	Your thread object begins running when the *Execute* method is called (see Executing thread objects (see page 2242)) and continues until *Execute* finishes. This reflects the model that the thread performs a specific task, and then stops when it is finished. Sometimes, however, an application needs a thread to execute until some external criterion is satisfied. You can allow other threads to signal that it is time for your thread to finish executing by checking the Terminated property. When another thread tries to terminate your thread, it calls the Terminate method. *Terminate* sets your thread's *Terminated* property to *True*. It is... more (see page 2232)
Defining Thread Objects (see page 2233)	For most applications, you can use a thread object to represent an execution thread in your application. Thread objects simplify writing multi-threaded applications by encapsulating the most commonly needed uses of threads. **Note:** Thread objects do not allow you to control the security attributes or stack size of your threads. If you need to control these, you must use the BeginThread function. Even when using *BeginThread*, you can still benefit from some of the thread synchronization objects and methods described in Coordinating Threads (see page 2227).
Handling Exceptions in the Thread Function (see page 2234)	The *Execute* method must catch all exceptions that occur in the thread. If you fail to catch an exception in your thread function, your application can cause access violations. This may not be obvious when you are developing your application, because the IDE catches the exception, but when you run your application outside of the debugger, the exception will cause a runtime error and the application will stop running. To catch the exceptions that occur inside your thread function, add a **try...except** block to the implementation of the *Execute* method:

Initializing the Thread (see page 2234)	If you want to write initialization code for your new thread class, you must override the *Create* method. Add a new constructor to the declaration of your thread class and write the initialization code as its implementation. This is where you can assign a default priority for your thread and indicate whether it should be freed automatically when it finishes executing.
Using the Main VCL Thread (see page 2235)	When you use objects from the class hierarchy, their properties and methods are not guaranteed to be thread-safe. That is, accessing properties or executing methods may perform some actions that use memory which is not protected from the actions of other threads. Because of this, a main thread is set aside to access VCL objects. This is the thread that handles all Windows messages received by components in your application. If all objects access their properties and execute their methods within this single thread, you need not worry about your objects interfering with each other. To use the main thread,... more (see page 2235)
Using Thread-local Variables (see page 2237)	The thread function and any of the routines it calls have their own local variables, just like any other Dephi language routines. These routines also can access any global variables. In fact, global variables provide a powerful mechanism for communicating between threads. Sometimes, however, you may want to use variables that are global to all the routines running in your thread, but not shared with other instances of the same thread class. You can do this by declaring thread-local variables. Make a variable thread-local by declaring it in a **threadvar** section (Delphi) or adding the **__thread** modifier (C++). For example,... more (see page 2237)
Writing Clean-up Code (see page 2237)	You can centralize the code that cleans up when your thread finishes executing. Just before a thread shuts down, an OnTerminate event occurs. Put any clean-up code in the *OnTerminate* event handler to ensure that it is always executed, no matter what execution path the Execute method follows. The *OnTerminate* event handler is not run as part of your thread. Instead, it is run in the context of the main VCL thread (see page 2235) of your application. This has two implications: • You can't use any thread-local variables (see page 2237) in an *OnTerminate* event handler (unless you want the main VCL thread values). • You can... more (see page 2237)
Writing the Thread Function (see page 2238)	The Execute method is your thread function. You can think of it as a program that is launched by your application, except that it shares the same process space. Writing the thread function is a little trickier than writing a separate program because you must make sure that you don't overwrite memory that is used by other threads in your application. On the other hand, because the thread shares the same process space with other threads, you can use the shared memory to communicate between threads. When implementing the *Execute* method, you can manage these issues by: • Using thread-local variables (see page 2237)... more (see page 2238)

3.2.4.15.3.1 Checking for Termination by Other Threads

Your thread object begins running when the *Execute* method is called (see Executing thread objects (see page 2242)) and continues until *Execute* finishes. This reflects the model that the thread performs a specific task, and then stops when it is finished. Sometimes, however, an application needs a thread to execute until some external criterion is satisfied.

You can allow other threads to signal that it is time for your thread to finish executing by checking the Terminated property. When another thread tries to terminate your thread, it calls the Terminate method. *Terminate* sets your thread's *Terminated* property to *True*. It is up to your Execute method to implement the *Terminate* method by checking and responding to the *Terminated* property. The following example shows one way to do this:

```
procedure TMyThread.Execute;
begin
while not Terminated do
PerformSomeTask;
end;
void __fastcall TMyThread::Execute()
{
while (!Terminated)
```

```
PerformSomeTask();
}
```

3.2.4.15.3.2 Defining Thread Objects

For most applications, you can use a thread object to represent an execution thread in your application. Thread objects simplify writing multi-threaded applications by encapsulating the most commonly needed uses of threads.

Note: Thread objects do not allow you to control the security attributes or stack size of your threads. If you need to control these, you must use the BeginThread function. Even when using *BeginThread*, you can still benefit from some of the thread synchronization objects and methods described in Coordinating Threads (see page 2227).

To use a thread object in your application

1. Create a new descendant of TThread, choose **File** ▶ **New** ▶ **Other** from the main menu.
2. In the New Items dialog box under Delphi Files, double-click Thread Object and enter a class name, such as *TMyThread*.
3. Check the Named Thread check box and enter a thread name (VCL applications only).
4. Click OK, the **Code Editor** creates a new unit file to implement the thread.

For more information on naming threads, see Naming a Thread (see page 2241).

Note: Unlike most dialog boxes in the IDE that require a class name, the New Thread Object dialog box does not automatically prepend a 'T' to the front of the class name you provide.

The automatically generated unit file contains the skeleton code for your new thread class. If you named your thread *TMyThread*, it would look like the following:

```
unit Unit2;
interface
uses
Classes;
type
TMyThread = class(TThread)
private
{ Private declarations }
protected
procedure Execute; override;
end;
implementation
{ TMyThread }
procedure TMyThread.Execute;
begin
{ Place thread code here }
end;
end.
//---------------------------------------------------------------------------
#include <vcl.h>
#pragma hdrstop
#include "Unit2.h"
#pragma package(smart_init)
//---------------------------------------------------------------------------
__fastcall TMyThread::TMyThread(bool CreateSuspended): TThread(CreateSuspended)
{
}
```

```
//---------------------------------------------------------------------------
void __fastcall TMyThread::Execute()
{
// ---- Place thread code here ----
}
//---------------------------------------------------------------------------
```

In the automatically generated unit file, you

- Optionally, initialize the thread (see page 2234).
- Write the thread function (see page 2238) by filling in the *Execute* method.
- Optionally, write clean-up code (see page 2237).

See Also

Executing Thread Objects (see page 2242)

3.2.4.15.3.3 Handling Exceptions in the Thread Function

The *Execute* method must catch all exceptions that occur in the thread. If you fail to catch an exception in your thread function, your application can cause access violations. This may not be obvious when you are developing your application, because the IDE catches the exception, but when you run your application outside of the debugger, the exception will cause a runtime error and the application will stop running.

To catch the exceptions that occur inside your thread function, add a **try...except** block to the implementation of the *Execute* method:

```
procedure TMyThread.Execute;
begin
  try
    while not Terminated do
  PerformSomeTask;
  except
    { do something with exceptions }
  end;
end;
void __fastcall TMyThread::Execute()
{
  try
  {
    while (!Terminated)
      PerformSomeTask();
  }
  catch (...)
  {
    // do something with exceptions
  }
}
```

Using Thread-local Variables (see page 2237)

Checking for Termination by Other Threads (see page 2232)

3.2.4.15.3.4 Initializing the Thread

If you want to write initialization code for your new thread class, you must override the *Create* method. Add a new constructor to the declaration of your thread class and write the initialization code as its implementation. This is where you can assign a default

priority for your thread and indicate whether it should be freed automatically when it finishes executing.

Assigning a default priority

Priority indicates how much preference the thread gets when the operating system schedules CPU time among all the threads in your application. Use a high priority thread to handle time critical tasks, and a low priority thread to perform other tasks. To indicate the priority of your thread object, set the Priority property.

If writing a Windows-only application, *Priority* values fall along a scale, as described in the following table:

Thread priorities

Value	Priority
tpIdle	The thread executes only when the system is idle. Windows won't interrupt other threads to execute a thread with *tpIdle* priority.
tpLowest	The thread's priority is two points below normal.
tpLower	The thread's priority is one point below normal.
tpNormal	The thread has normal priority.
tpHigher	The thread's priority is one point above normal.
tpHighest	The thread's priority is two points above normal.
tpTimeCritical	The thread gets highest priority.

Warning: Boosting the thread priority of a CPU intensive operation may "starve" other threads in the application. Only apply priority boosts to threads that spend most of their time waiting for external events.

The following code shows the constructor of a low-priority thread that performs background tasks which should not interfere with the rest of the application's performance:

```
constructor TMyThread.Create(CreateSuspended: Boolean);
begin
  inherited Create(CreateSuspended);
Priority := tpIdle;
end;
//---------------------------------------------------------------------------
__fastcall TMyThread::TMyThread(bool CreateSuspended): TThread(CreateSuspended)
{
Priority = tpIdle;
}
//---------------------------------------------------------------------------
```

Indicating when threads are freed

Usually, when threads finish their operation, they can simply be freed. In this case, it is easiest to let the thread object free itself. To do this, set the FreeOnTerminate property to *True*.

There are times, however, when the termination of a thread must be coordinated with other threads. For example, you may be waiting for one thread to return a value before performing an action in another thread. To do this, you do not want to free the first thread until the second has received the return value. You can handle this situation by setting *FreeOnTerminate* to *False* and then explicitly freeing the first thread from the second.

See Also

Writing the Thread Function (see page 2238)

Writing Clean-up Code (see page 2237)

3.2.4.15.3.5 Using the Main VCL Thread

When you use objects from the class hierarchy, their properties and methods are not guaranteed to be thread-safe. That is,

accessing properties or executing methods may perform some actions that use memory which is not protected from the actions of other threads. Because of this, a main thread is set aside to access VCL objects. This is the thread that handles all Windows messages received by components in your application.

If all objects access their properties and execute their methods within this single thread, you need not worry about your objects interfering with each other. To use the main thread, create a separate routine that performs the required actions. Call this separate routine from within your thread's Synchronize method. For example:

```
procedure TMyThread.PushTheButton;
begin
Button1.Click;
end;
...
procedure TMyThread.Execute;
begin
...
Synchronize(PushTheButton);
...
end;
void __fastcall TMyThread::PushTheButton(void)
{
Button1->Click();
}
void __fastcall TMyThread::Execute()
{
...
Synchronize((TThreadMethod)PushTheButton);
...
}
```

Synchronize waits for the main thread to enter the message loop and then executes the passed method.

Note: Because *Synchronize* uses the message loop, it does not work in console applications. You must use other mechanisms, such as critical sections, to protect access to VCL objects in console applications.

You do not always need to use the main thread. Some objects are thread-aware. Omitting the use of the *Synchronize* method when you know an object's methods are thread-safe will improve performance because you don't need to wait for the VCL thread to enter its message loop. You do not need to use the *Synchronize* method for the following objects:

Object	Description
Data access component	Data access components are thread-safe as follows: For BDE-enabled datasets, each thread must have its own database session component. The one exception to this is when you are using Microsoft Access drivers, which are built using a Microsoft library that is not thread-safe. For dbExpress, as long as the vendor client library is thread-safe, the dbExpress components will be thread-safe. ADO and InterBaseExpress components are thread-safe. When using data access components, you must still wrap all calls that involve data-aware controls in the *Synchronize* method. Thus, for example, you need to synchronize calls that link a data control to a dataset by setting the *DataSet* property of the data source object, but you don't need to synchronize to access the data in a field of the dataset. For more information about using database sessions with threads in BDE-enabled applications, see Managing multiple sessions (see page 1659).
Control	Controls are not thread-safe.
Graphic	Graphics objects are thread-safe. You do not need to use the main VCL thread to access TFont, TPen, TBrush, TBitmap, TMetafile (VCL only), or TTIcon. Canvas objects can be used outside the *Synchronize* method by locking them (see page 2227).
List	While list objects are not thread-safe, you can use a thread-safe version, TThreadList, instead of *TList*.

Call the *CheckSynchronize* routine periodically within the main thread of your application so that background threads can synchronize their execution with the main thread. The best place to call *CheckSynchronize* is when the application is idle (for

example, from an *OnIdle* event handler). This ensures that it is safe to make method calls in the background thread.

Using Thread-local Variables (see page 2237)

Waiting for Other Threads (see page 2230)

Checking for Termination by Other Threads (see page 2232)

Handling Exceptions in the Thread Function (see page 2234)

3.2.4.15.3.6 Using Thread-local Variables

The thread function and any of the routines it calls have their own local variables, just like any other Dephi language routines. These routines also can access any global variables. In fact, global variables provide a powerful mechanism for communicating between threads.

Sometimes, however, you may want to use variables that are global to all the routines running in your thread, but not shared with other instances of the same thread class. You can do this by declaring thread-local variables. Make a variable thread-local by declaring it in a **threadvar** section (Delphi) or adding the **__thread** modifier (C++). For example,

```
threadvar
x : integer;
```

```
int __thread x;
```

declares an integer type variable that is private to each thread in the application, but global within each thread.

The threadvar section can only be used for global variables. Pointer and Function variables can't be thread variables. Types that use copy-on-write semantics, such as long strings don't work as thread variables either.

In C++, the following declarations require runtime initialization and are therefore illegal:

```
int f( );
int __thread x = f( );   // illegal
```

Instantiation of a class with a user-defined constructor or destructor requires runtime initialization and is therefore illegal:

```
class X {
    X( );
    ~X( );
};
X __thread myclass;         // illegal
```

Waiting for Other Threads (see page 2230)

Checking for Termination by Other Threads (see page 2232)

Handling Exceptions in the Thread Function (see page 2234)

3.2.4.15.3.7 Writing Clean-up Code

You can centralize the code that cleans up when your thread finishes executing. Just before a thread shuts down, an OnTerminate event occurs. Put any clean-up code in the *OnTerminate* event handler to ensure that it is always executed, no matter what execution path the Execute method follows.

The *OnTerminate* event handler is not run as part of your thread. Instead, it is run in the context of the main VCL thread (see page 2235) of your application. This has two implications:

- You can't use any thread-local variables (see page 2237) in an *OnTerminate* event handler (unless you want the main VCL

thread values).

- You can safely access any objects from the *OnTerminate* event handler without worrying about clashing with other threads.

See Also

Initializing the Thread (see page 2234)

Writing the Thread Function (see page 2238)

3.2.4.15.3.8 Writing the Thread Function

The Execute method is your thread function. You can think of it as a program that is launched by your application, except that it shares the same process space. Writing the thread function is a little trickier than writing a separate program because you must make sure that you don't overwrite memory that is used by other threads in your application. On the other hand, because the thread shares the same process space with other threads, you can use the shared memory to communicate between threads.

When implementing the *Execute* method, you can manage these issues by:

- Using thread-local variables (see page 2237)
- Avoiding simultaneous access (see page 2226)
- Waiting for other threads (see page 2230)
- Checking for termination by other threads (see page 2232)
- Handling exceptions in the thread function (see page 2234)

Topics

Name	Description
Assigning Separate Names to Similar Threads (see page 2239)	All thread instances from the same thread class have the same name. However, you can assign a different name for each thread instance at runtime using the following steps.
Converting an Unnamed Thread to a Named Thread (see page 2239)	You can convert an unnamed thread to a named thread. For example, if you have a thread class that was created using Delphi 6 or earlier, convert it into a named thread.
Naming a Thread (see page 2241)	Because it is difficult to tell which thread ID refers to which thread in the Thread Status box, you can name your thread classes. When you are creating a thread class in the Thread Object dialog box, besides entering a class name, also check the Named Thread check box, enter a thread name, and click OK. Naming the thread class adds a method to your thread class called *SetName*. When the thread starts running, it calls the *SetName* method first. **Note:** You can name threads in VCL applications only. You can also: • Convert an unnamed thread to a named (see page 2239)... more (see page 2241)
Debugging Multi-threaded Applications (see page 2241)	When debugging multi-threaded applications, it can be confusing trying to keep track of the status of all the threads that are executing simultaneously, or even to determine which thread is executing when you stop at a breakpoint. You can use the Thread Status box to help you keep track of and manipulate all the threads in your application. To display the Thread status box, choose **View ▶ Debug Windows ▶ Threads** from the main menu. When a debug event occurs (breakpoint, exception, paused), the thread status view indicates the status of each thread. Right-click the Thread Status box to access commands that... more (see page 2241)

Executing Thread Objects (see page 2242)	Once you have implemented a thread class by giving it an *Execute* method, you can use it in your application to launch the code in the *Execute* method. To use a thread, first create an instance of the thread class. You can create a thread instance that starts running immediately, or you can create your thread in a suspended state so that it only begins when you call the Resume method. To create a thread so that it starts up immediately, set the constructor's *CreateSuspended* parameter to *False*. For example, the following line creates a thread and starts its... more (see page 2242)
Overriding the Default Priority (see page 2242)	When the amount of CPU time the thread should receive is implicit in the thread's task, its priority is set in the constructor. This is described in Initializing the thread (see page 2234). However, if the thread priority varies depending on when the thread is executed, create the thread in a suspended state, set the priority, and then start the thread running:
Starting and Stopping Threads (see page 2242)	A thread can be started and stopped any number of times before it finishes executing. To stop a thread temporarily, call its Suspend method. When it is safe for the thread to resume, call its Resume method. *Suspend* increases an internal counter, so you can nest calls to *Suspend* and *Resume*. The thread does not resume execution until all suspensions have been matched by a call to *Resume*. You can request that a thread end execution prematurely by calling the Terminate method. *Terminate* sets the thread's Terminated property to *True*. If you have implemented the *Execute* method... more (see page 2242)

3.2.4.15.4.1 Assigning Separate Names to Similar Threads

All thread instances from the same thread class have the same name. However, you can assign a different name for each thread instance at runtime using the following steps.

To assign separate names to similar threads

1. Add a *ThreadName* property to the thread class by adding the following in the class definition:

```
property ThreadName: string read FName write FName;
__property AnsiString ThreadName = {read=FName, write=FName};
```

2. In the *SetName* method, change where it says:

```
ThreadNameInfo.FName := 'MyThreadName';
info.szName = "MyThreadName";
```

to:

```
ThreadNameInfo.FName := ThreadName;
info.szName = ThreadName;
```

To create the thread object

1. Create it suspended. See Executing Thread Objects (see page 2242).
2. Assign a name, such as `MyThread.ThreadName := 'SearchForFiles';`
3. Resume the thread. See Starting and Stopping Threads (see page 2242).

See Also

Converting an Unnamed Thread to a Named Thread (see page 2239)

Naming a Thread (see page 2241)

3.2.4.15.4.2 Converting an Unnamed Thread to a Named Thread

You can convert an unnamed thread to a named thread. For example, if you have a thread class that was created using Delphi 6 or earlier, convert it into a named thread.

To convert an unnamed thread to a named thread

1. Add the Windows unit to the **uses** clause of the unit your thread is declared in:

```
//---------------------------------------------------------------------------
```

```
uses
Classes {$IFDEF MSWINDOWS} , Windows {$ENDIF};
//---------------------------------------------------------------------------
```

2. Add the *SetName* method to your thread class in the **interface** section:

```
//---------------------------------------------------------------------------
type
TMyThread = class(TThread)
private
procedure SetName;
protected
procedure Execute; override;
end;
//---------------------------------------------------------------------------
//---------------------------------------------------------------------------
void TMyThread::SetName()
{
THREADNAME_INFO info;
info.dwType = 0x1000;
info.szName = "MyThreadName";
info.dwThreadID = -1;
info.dwFlags = 0;
__try
{
RaiseException( 0x406D1388, 0, sizeof(info)/sizeof(DWORD),(DWORD*)&info );
}
__except (EXCEPTION_CONTINUE_EXECUTION)
{
}
}
//---------------------------------------------------------------------------
```

3. Add the *TThreadNameInfo* record and *SetName* method in the **implementation** section:

```
//---------------------------------------------------------------------------
{$IFDEF MSWINDOWS}
type
TThreadNameInfo = record
FType: LongWord;     // must be 0x1000
FName: PChar;        // pointer to name (in user address space)
FThreadID: LongWord; // thread ID (-1 indicates caller thread)
FFlags: LongWord;    // reserved for future use, must be zero
  end;
{$ENDIF}
{ TMyThread }
procedure TMyThread.SetName;
{$IFDEF MSWINDOWS}
var
ThreadNameInfo: TThreadNameInfo;
{$ENDIF}
begin
{$IFDEF MSWINDOWS}
ThreadNameInfo.FType := $1000;
ThreadNameInfo.FName := 'MyThreadName';
ThreadNameInfo.FThreadID := $FFFFFFFF;
ThreadNameInfo.FFlags := 0;
try
RaiseException( $406D1388, 0, sizeof(ThreadNameInfo) div sizeof(LongWord), @ThreadNameInfo );
 except
  end;
{$ENDIF}
end;
//---------------------------------------------------------------------------
```

Note: Set *TThreadNameInfo* to the name of your thread class.

The debugger sees the exception and looks up the thread name in the structure you pass in. When debugging, the debugger

displays the name of the thread in the Thread Status box's thread ID field.

4. Add a call to the new *SetName* method at the beginning of your thread's *Execute* method:

```
//---------------------------------------------------------------------------
procedure TMyThread.Execute;
begin
SetName;
{ Place thread code here }
end;
//---------------------------------------------------------------------------
//---------------------------------------------------------------------------
void __fastcall TMyThread::Execute()
{
SetName();
//---- Place existing Execute method code here ----
}
//---------------------------------------------------------------------------
```

See Also

Naming a Thread (see page 2241)

Assigning Separate Names to Similar Threads (see page 2239)

3.2.4.15.4.3 Naming a Thread

Because it is difficult to tell which thread ID refers to which thread in the Thread Status box, you can name your thread classes. When you are creating a thread class in the Thread Object dialog box, besides entering a class name, also check the Named Thread check box, enter a thread name, and click OK.

Naming the thread class adds a method to your thread class called *SetName*. When the thread starts running, it calls the *SetName* method first.

Note: You can name threads in VCL applications only.

You can also:

- Convert an unnamed thread to a named thread (see page 2239).
- Assign separate names to similar threads (see page 2239).

See Also

Executing Thread Objects (see page 2242)

Defining Thread Objects (see page 2233)

Converting an Unnamed Thread to a Named Thread (see page 2239)

3.2.4.15.4.4 Debugging Multi-threaded Applications

When debugging multi-threaded applications, it can be confusing trying to keep track of the status of all the threads that are executing simultaneously, or even to determine which thread is executing when you stop at a breakpoint. You can use the Thread Status box to help you keep track of and manipulate all the threads in your application. To display the Thread status box, choose **View** ▸ **Debug Windows** ▸ **Threads** from the main menu.

When a debug event occurs (breakpoint, exception, paused), the thread status view indicates the status of each thread. Right-click the Thread Status box to access commands that locate the corresponding source location or make a different thread current. When a thread is marked as current, the next step or run operation is relative to that thread.

The Thread Status box lists all your application's execution threads by their thread ID. If you are using thread objects, the thread ID is the value of the *ThreadID* property. If you are not using thread objects, the thread ID for each thread is returned by the call to *BeginThread*.

See Also

Executing Thread Objects (see page 2242)

Defining Thread Objects (see page 2233)

Defining Thread Objects (see page 2233)

Naming a Thread (see page 2241)

Starting and Stopping Threads (see page 2242)

3.2.4.15.4.5 Executing Thread Objects

Once you have implemented a thread class by giving it an *Execute* method, you can use it in your application to launch the code in the *Execute* method. To use a thread, first create an instance of the thread class. You can create a thread instance that starts running immediately, or you can create your thread in a suspended state so that it only begins when you call the Resume method. To create a thread so that it starts up immediately, set the constructor's *CreateSuspended* parameter to *False*. For example, the following line creates a thread and starts its execution:

```
SecondThread := TMyThread.Create(false); {create and run the thread }
TMyThread *SecondThread = new TMyThread(false); // create and run the thread
```

Warning: Do not create too many threads in your application. The overhead in managing multiple threads can impact performance. The recommended limit is 16 threads per process on single processor systems. This limit assumes that most of those threads are waiting for external events. If all threads are active, you will want to use fewer.

You can create multiple instances of the same thread type to execute parallel code. For example, you can launch a new instance of a thread in response to some user action, allowing each thread to perform the expected response.

The following topics discuss how to use the threads in your application:

- Overriding the Default Priority (see page 2242).
- Starting and Stopping Threads (see page 2242)

See Also

Defining Thread Objects (see page 2233)

3.2.4.15.4.6 Overriding the Default Priority

When the amount of CPU time the thread should receive is implicit in the thread's task, its priority is set in the constructor. This is described in Initializing the thread (see page 2234). However, if the thread priority varies depending on when the thread is executed, create the thread in a suspended state, set the priority, and then start the thread running:

```
SecondThread :=  TMyThread.Create(True); { create but don't run }
SecondThread.Priority := tpLower; { set the priority lower than normal }
SecondThread.Resume; { now run the thread }
TMyThread *SecondThread = new TMyThread(true); // create but don't run
SecondThread->Priority = tpLower; // set the priority lower than normal
SecondThread->Resume(); // now run the thread
```

See Also

Starting and Stopping Threads (see page 2242)

3.2.4.15.4.7 Starting and Stopping Threads

A thread can be started and stopped any number of times before it finishes executing. To stop a thread temporarily, call its Suspend method. When it is safe for the thread to resume, call its Resume method. *Suspend* increases an internal counter, so you can nest calls to *Suspend* and *Resume*. The thread does not resume execution until all suspensions have been matched by

a call to *Resume*.

You can request that a thread end execution prematurely by calling the Terminate method. *Terminate* sets the thread's Terminated property to *True*. If you have implemented the *Execute* method properly, it checks the *Terminated* property periodically, and stops execution when *Terminated* is *True*.

Overriding the Default Priority (see page 2242)

Checking for Termination by Other Threads (see page 2232)

3.2.5 Writing Internet Applications

Contains the Developer's Guide topics for writing internet applications in Delphi.

Topics

Name	Description
Creating Internet server applications (see page 2243)	
Using IntraWeb (VCL for the Web) (see page 2254)	For more documentation on VCL for the Web, go to http://www.atozed.com/intraweb/docs/.
Using Web Broker (see page 2261)	
Using Web Services (see page 2289)	
Using WebSnap (see page 2310)	WebSnap is being deprecated in RAD Studio. Although WebSnap is still documented in the online help, the WebSnap product is no longer fully supported. As an alternative, you should begin using IntraWeb (VCL for the Web). IntraWeb (see page 2254) is documented in this online help. For more documentation on VCL for the Web, go to http://www.atozed.com/intraweb/docs/.
Working with sockets (see page 2335)	
Working with XML documents (see page 2351)	

3.2.5.1 Creating Internet server applications

Topics

Name	Description
Debugging server applications (see page 2244)	
About Web Broker and WebSnap (see page 2246)	Part of the function of any application is to make data accessible to the user. In a standard application you accomplish this by creating traditional front end elements, like dialogs and scrolling windows. Developers can specify the exact layout of these objects using familiar form design tools. Web server applications must be designed differently, however. All information passed to users must be in the form of HTML pages which are transferred through HTTP. Pages are generally interpreted on the client machine by a Web browser application, which displays the pages in a form appropriate for the user's particular system in... more (see page 2246)
HTTP server activity (see page 2247)	
Creating Internet Applications: Overview (see page 2251)	Web server applications extend the functionality and capability of existing Web servers. A Web server application receives HTTP request messages from the Web server, performs any actions requested in those messages, and formulates responses that it passes back to the Web server. Many operations that you can perform with an ordinary application can be incorporated into a Web server application. The IDE provides two different architectures for developing Web server applications: Web Broker and WebSnap. Although these two architectures are different, WebSnap and Web Broker have many common elements. The WebSnap architecture acts as a superset of Web Broker. It... more (see page 2251)
Terminology and standards (see page 2252)	

3.2.5.1.1 Debugging server applications

Topics

Name	Description
Debugging Web Applications That Are DLLs (see page 2244)	ISAPI, NSAPI, and Apache applications are actually DLLs that contain predefined entry points. The Web server passes request messages to the application by making calls to these entry points. Because these applications are DLLs, you can debug them by setting your application's run parameters to launch the server. To set up your application's run parameters, choose **Run ▶ Parameters** and set the Host Application and Run Parameters to specify the executable for the Web server and any parameters it requires when you launch it. For details about these values on your Web server, see the documentation provided by you Web server... more (see page 2244)
Debugging Server Applications (see page 2245)	Debugging Web server applications presents some unique problems, because they run in response to messages from a Web server. You can not simply launch your application from the IDE, because that leaves the Web server out of the loop, and your application will not find the request message it is expecting. The following topics describe techniques you can use to debug Web server applications: • Using the Web Application Debugger (see page 2245) • Debugging Web Applications that are DLLs (see page 2244)
Using the Web Application Debugger (see page 2245)	The Web Application Debugger provides an easy way to monitor HTTP requests, responses, and response times. The Web Application Debugger takes the place of the Web server. Once you have debugged your application, you can convert it to one of the supported types of Web application and install it with a commercial Web server. To use the Web Application Debugger, you must first create your Web application as a Web Application Debugger executable. Whether you are using Web Broker or WebSnap, the wizard that creates your Web server application includes this as an option when you first begin the application.... more (see page 2245)

3.2.5.1.1.1 Debugging Web Applications That Are DLLs

ISAPI, NSAPI, and Apache applications are actually DLLs that contain predefined entry points. The Web server passes request messages to the application by making calls to these entry points. Because these applications are DLLs, you can debug them by setting your application's run parameters to launch the server.

To set up your application's run parameters, choose **Run ▶ Parameters** and set the Host Application and Run Parameters to specify the executable for the Web server and any parameters it requires when you launch it. For details about these values on your Web server, see the documentation provided by you Web server vendor.

Note: Some Web Servers require additional changes before you have the rights to launch the Host Application in this way. See your Web server vendor for details.

Tip: If you are using Windows 2000 with IIS 5, details on all of the changes you need to make to set up your rights properly are described at the following Web site:

`http://community.borland.com/article/0,1410,23024,00.html`

Once you have set the Host Application and Run Parameters, you can set up your breakpoints so that when the server passes a request message to your DLL, you hit one of your breakpoints, and can debug normally.

Note: Before launching the Web server using your application's run parameters, make sure that the server is not already running.

User rights necessary for DLL debugging

Under Windows, you must have the correct user rights to debug a DLL.

To obtain these rights

1. In the Administrative Tools portion of the Control Panel, click on Local Security Policy. Expand Local Policies and double-click User Rights Assignment. Double-click Act as part of the operating system in the right-hand panel.
2. Select Add to add a user to the list. Add your current user.
3. Reboot so the changes take effect.

See Also

HTTP Server Activity (see page 2248)

3.2.5.1.1.2 Debugging Server Applications

Debugging Web server applications presents some unique problems, because they run in response to messages from a Web server. You can not simply launch your application from the IDE, because that leaves the Web server out of the loop, and your application will not find the request message it is expecting.

The following topics describe techniques you can use to debug Web server applications:

- Using the Web Application Debugger (see page 2245)
- Debugging Web Applications that are DLLs (see page 2244)

See Also

Creating Web Server Applications (see page 2313)

The Structure of a Web Broker Application (see page 2286)

Types of Web Server Applications (see page 2249)

3.2.5.1.1.3 Using the Web Application Debugger

The Web Application Debugger provides an easy way to monitor HTTP requests, responses, and response times. The Web Application Debugger takes the place of the Web server. Once you have debugged your application, you can convert it to one of the supported types of Web application and install it with a commercial Web server.

To use the Web Application Debugger, you must first create your Web application as a Web Application Debugger executable. Whether you are using Web Broker or WebSnap, the wizard that creates your Web server application includes this as an option when you first begin the application. This creates a Web server application that is also a COM server.

For information on how to write this Web server application using Web Broker, see Using Web Broker (see page 2272). For more information on using WebSnap, see Creating Web Server applications using WebSnap (see page 2315).

Launching your application with the Web Application Debugger

Once you have developed your Web server application, you can run and debug it.

To launch your application with the Web Application Debugger

1. With your project loaded in the IDE, set any breakpoints so that you can debug your application just like any other executable.
2. Choose **Run** ▸ **Run**. This displays the console window of the COM server that is your Web server application. The first time you run your application, it registers your COM server so that the Web App debugger can access it.
3. Select **Tools** ▸ **Web App Debugger**.
4. Click the Start button. This displays the ServerInfo page in your default Browser.

5. The ServerInfo page provides a drop-down list of all registered Web Application Debugger executables. Select your application from the drop-down list. If you do not find your application in this drop-down list, try running your application as an executable. Your application must be run once so that it can register itself. If you still do not find your application in the drop-down list, try refreshing the Web page. (Sometimes the Web browser caches this page, preventing you from seeing the most recent changes.)
6. Once you have selected your application in the drop-down list, press the Go button. This launches your application in the Web Application Debugger, which provides you with details on request and response messages that pass between your application and the Web Application Debugger.

Converting your application to another type of Web server application

When you have finished debugging your Web server application with the Web Application Debugger, you will need to convert it to another type that can be installed on a commercial Web server. To learn more about converting your application, see "Converting Web server application target types" in the topic Types of Web server applications (see page 2249).

Debugging Web Applications That Are DLLs (see page 2244)

HTTP Server Activity (see page 2248)

3.2.5.1.2 About Web Broker and WebSnap

Part of the function of any application is to make data accessible to the user. In a standard application you accomplish this by creating traditional front end elements, like dialogs and scrolling windows. Developers can specify the exact layout of these objects using familiar form design tools. Web server applications must be designed differently, however. All information passed to users must be in the form of HTML pages which are transferred through HTTP. Pages are generally interpreted on the client machine by a Web browser application, which displays the pages in a form appropriate for the user's particular system in its present state.

The first step in building a Web server application is choosing which architecture you want to use, Web Broker or WebSnap. Both approaches provide many of the same features, including

- Support for CGI and Apache DSO Web server application types. These are described in Types of Web Server Applications (see page 2249).
- Multithreading support so that incoming client requests are handled on separate threads.
- Caching of Web modules for quicker responses.

Both the Web Broker and WebSnap components handle all of the mechanics of page transfer. WebSnap uses Web Broker as its foundation, so it incorporates all of the functionality of Web Broker's architecture. WebSnap offers a much more powerful set of tools for generating pages, however. Also, WebSnap applications allow you to use server-side scripting to help generate pages at runtime. Web Broker does not have this scripting capability. The tools offered in Web Broker are not nearly as complete as those in WebSnap, and are much less intuitive. If you are developing a new Web server application, WebSnap is probably a better choice of architecture than Web Broker.

The major differences between these two approaches are outlined in the following table:

Web Broker versus WebSnap

Web Broker	WebSnap
Backward compatible	Although WebSnap applications can use any Web Broker components that produce content, the Web modules and dispatcher that contain these are new.
Only one Web module allowed in an application.	Multiple Web modules can partition the application into units, allowing multiple developers to work on the same project with fewer conflicts.
Only one Web dispatcher allowed in the application.	Multiple, special-purpose dispatchers handle different types of requests.

Specialized components for creating content include page producers, InternetExpress components, and Web Services components.	Supports all the content producers that can appear in Web Broker applications, plus many others designed to let you quickly build complex data-driven Web pages.
No scripting support.	Support for server-side scripting allows HTML generation logic to be separated from the business logic.
No built-in support for named pages.	Named pages can be automatically retrieved by a page dispatcher and addressed from server-side scripts.
No session support.	Sessions store information about an end user that is needed for a short period of time. This can be used for such tasks as login/logout support.
Every request must be explicitly handled, using either an action item or an auto-dispatching component.	Dispatch components automatically respond to a variety of requests.
Only a few specialized components provide previews of the content they produce. Most development is not visual.	WebSnaplets you build Web pages more visually and view the results at design time. Previews are available for all components.

For more information on Web Broker, see Using Web Broker. (see page 2272) For more information on WebSnap, see Creating Web Server Applications Using WebSnap (see page 2315).

3.2.5.1.3 HTTP server activity

Topics

Name	Description
Composing Client Requests (see page 2248)	When an HTML hypertext link is selected (or the user otherwise specifies a URL), the browser collects information about the protocol, the specified domain, the path to the information, the date and time, the operating environment, the browser itself, and other content information. It then composes a request. For example, to display a page of images based on criteria selected by clicking buttons on a form, the client might construct this URL:
HTTP Server Activity (see page 2248)	The client/server nature of Web browsers is deceptively simple. To most users, retrieving information on the World Wide Web is a simple procedure: click on a link, and the information appears on the screen. More knowledgeable users have some understanding of the nature of HTML syntax and the client/server nature of the protocols used. This is usually sufficient for the production of simple, page-oriented Web site content. Authors of more complex Web pages have a wide variety of options to automate the collection and presentation of information using HTML. Before building a Web server application, it is useful to understand... more (see page 2248)
Responding to Client Requests (see page 2249)	When a Web server application finishes with a client request, it constructs a page of HTML code or other MIME content, and passes it back (via the server) to the client for display. The way the response is sent may differ based on the type of program. When a DLL finishes, it passes the HTML page and any response information directly back to the server, which passes them back to the client. Creating a Web server application as a DLL reduces system load and resource use by reducing the number of processes and disk accesses necessary to service an individual... more (see page 2249)

Serving Client Requests (see page 2249)	The Web server receives a client request and can perform any number of actions, based on its configuration. If the server is configured to recognize the /gallery.dll portion of the request as a program, it passes information about the request to that program. The way information about the request is passed to the program depends on the type of Web server application: • If the program is a Common Gateway Interface (CGI) program, the server passes the information contained in the request directly to the CGI program. The server waits while the program executes. When the CGI program exits, it passes... more (see page 2249)
Types of Web Server Applications (see page 2249)	Whether you use Web Broker or WebSnap, you can create five standard types of Web server applications. In addition, you can create a Web Application Debugger executable, which integrates the Web server into your application so that you can debug your application logic. The Web Application Debugger executable is intended only for debugging. When you deploy your application, you should migrate to one of the other five types.

3.2.5.1.3.1 Composing Client Requests

When an HTML hypertext link is selected (or the user otherwise specifies a URL), the browser collects information about the protocol, the specified domain, the path to the information, the date and time, the operating environment, the browser itself, and other content information. It then composes a request.

For example, to display a page of images based on criteria selected by clicking buttons on a form, the client might construct this URL:

```
http://www.TSite.com/art/gallery.dll/animals?animal=dog&color=black
```

which specifies an HTTP server in the www.TSite.com domain. The client contacts www.TSite.com, connects to the HTTP server, and passes it a request. The request might look something like this:

```
GET /art/gallery.dll/animals?animal=dog&color=black HTTP/1.0
Connection: Keep-Alive
User-Agent: Mozilla/3.0b4Gold (WinNT; I)
Host: www.TSite.com:1024
Accept: image/gif, image/x-xbitmap, image/jpeg, image/pjpeg, */*
```

Serving Client Requests (see page 2249)

Responding to Client Requests (see page 2249)

HTTP Request Header Information (see page 2252)

Parts of a Uniform Resource Locator (see page 2253)

3.2.5.1.3.2 HTTP Server Activity

The client/server nature of Web browsers is deceptively simple. To most users, retrieving information on the World Wide Web is a simple procedure: click on a link, and the information appears on the screen. More knowledgeable users have some understanding of the nature of HTML syntax and the client/server nature of the protocols used. This is usually sufficient for the production of simple, page-oriented Web site content. Authors of more complex Web pages have a wide variety of options to automate the collection and presentation of information using HTML.

Before building a Web server application, it is useful to understand how the client issues a request and how the server responds to client requests:

- Composing client requests (see page 2248)
- Serving client requests (see page 2249)
- Responding to client requests (see page 2249)

Terminology and Standards (see page 2253)

Creating Internet Applications: Overview (see page 2251)

Debugging Server Applications (see page 2245)

3.2.5.1.3.3 Responding to Client Requests

When a Web server application finishes with a client request, it constructs a page of HTML code or other MIME content, and passes it back (via the server) to the client for display. The way the response is sent may differ based on the type of program.

When a DLL finishes, it passes the HTML page and any response information directly back to the server, which passes them back to the client. Creating a Web server application as a DLL reduces system load and resource use by reducing the number of processes and disk accesses necessary to service an individual request.

See Also

Composing Client Requests (see page 2248)

Serving Client Requests (see page 2249)

Types of Web Server Applications (see page 2249)

3.2.5.1.3.4 Serving Client Requests

The Web server receives a client request and can perform any number of actions, based on its configuration. If the server is configured to recognize the /gallery.dll portion of the request as a program, it passes information about the request to that program. The way information about the request is passed to the program depends on the type of Web server application:

- If the program is a Common Gateway Interface (CGI) program, the server passes the information contained in the request directly to the CGI program. The server waits while the program executes. When the CGI program exits, it passes the content directly back to the server.
- If the program is a dynamic-link library (DLL), the server loads the DLL (if necessary) and passes the information contained in the request to the DLL as a structure. The server waits while the program executes. When the DLL exits, it passes the content directly back to the server.

In all cases, the program acts on the request of and performs actions specified by the programmer: accessing databases, doing simple table lookups or calculations, constructing or selecting HTML documents, and so on.

See Also

Composing Client Requests (see page 2248)

Responding to Client Requests (see page 2249)

Types of Web Server Applications (see page 2249)

3.2.5.1.3.5 Types of Web Server Applications

Whether you use Web Broker or WebSnap, you can create five standard types of Web server applications. In addition, you can create a Web Application Debugger executable, which integrates the Web server into your application so that you can debug your application logic. The Web Application Debugger executable is intended only for debugging. When you deploy your application, you should migrate to one of the other five types.

ISAPI and NSAPI

An ISAPI or NSAPI Web server application is a DLL that is loaded by the Web server. Client request information is passed to the DLL as a structure and evaluated by the ISAPI/NSAPI application, which creates appropriate request and response objects. Each request message is automatically handled in a separate execution thread.

CGI stand-alone

A CGI stand-alone Web server application is a console application that receives client request information on standard input and passes the results back to the server on standard output. This data is evaluated by the CGI application, which creates appropriate request and response objects. Each request message is handled by a separate instance of the application.

Apache

An Apache Web server application is a DLL that is loaded by the Web server. Client request information is passed to the DLL as a structure and evaluated by the Apache Web server application, which creates appropriate request and response objects. Each request message is automatically handled in a separate execution thread. You can build your Web server applications using Apache 1 or 2 as your target type.

When you deploy your Apache Web server application, you will need to specify some application-specific information in the Apache configuration files. For example, in Apache 1 projects the default module name is the project name with _module appended to the end. For example, a project named Project1 would have Project1_module as its module name. Similarly, the default content type is the project name with -content appended, and the default handler type is the project name with-handler appended.

These definitions can be changed in the project (.dpr) file when necessary. For example, when you create your project a default module name is stored in the project file. Here is a common example:

```
exports
apache_module name 'Project1_module';
extern "C"
{
Httpd::module __declspec(dllexport) Project1_module;
}
```

Note: When you rename the project during the save process, that name isn't changed automatically. Whenever you rename your project, you must change the module name in your project file to match your project name. The content and handler definitions should change automatically once the module name is changed.

For information on using module, content, and handler definitions in your Apache configuration files, see the documentation on the Apache Web site httpd.apache.org.

Web App Debugger

The server types mentioned above have their advantages and disadvantages for production environments, but none of them is well-suited for debugging. Deploying your application and configuring the debugger can make Web server application debugging far more tedious than debugging other application types.

Fortunately, Web server application debugging doesn't need to be that complicated. The IDE includes a Web App Debugger which makes debugging simple. The Web App Debugger acts like a Web server on your development machine. If you build your Web server application as a Web App Debugger executable, deployment happens automatically during the build process. To debug your application, start it using **Run ▸ Run**. Next, select **Tools ▸ Web App Debugger**, click the default URL and select your application in the Web browser which appears. Your application will launch in the browser window, and you can use the IDE to set breakpoints and obtain debugging information.

When your application is ready to be tested or deployed in a production environment, you can convert your Web App Debugger project to one of the other target types using the steps given below.

Note: When you create a Web App Debugger project, you will need to provide a CoClass Name for your project. This is simply a name used by the Web App Debugger to refer to your application. Most developers use the application's name as the CoClass Name.

Converting Web server application target types

One powerful feature of Web Broker and WebSnap is that they offer several different target server types. The IDE allows you to easily convert from one target type to another.

Because Web Broker and WebSnap have slightly different design philosophies, you must use a different conversion method for each architecture.

To convert your Web Broker application target type

1. Right-click the Web module and choose Add To Repository.
2. In the Add To Repository dialog box, give your Web module a title, text description, Repository page (probably Data Modules), author name, and icon.
3. Choose OK to save your Web module as a template.
4. From the main menu, choose **File** ▶ **New** and select Web Server Application. In the New Web Server Application dialog box, choose the appropriate target type.
5. Delete the automatically generated Web module.
6. From the main menu, choose **File** ▶ **New** and select the template you saved in step 3. This will be on the page you specified in step 2.

To convert a WebSnap application's target type

1. Open your project in the IDE.
2. Display the **Project Manager** using **View** ▶ **Project Manager**. Expand your project so all of its units are visible.
3. In the Project Manager, click the New button to create a new Web server application project. Double-click the WebSnap Application item in the WebSnap tab. Select the appropriate options for your project, including the server type you want to use, then click OK.
4. Expand the new project in the Project Manager. Select any files appearing there and delete them.
5. One at a time, select each file in your project (except for the form file in a Web App Debugger project) and drag it to the new project. When a dialog appears asking if you want to add that file to your new project, click Yes.

Creating Web Server Applications (see page 2313)

The Structure of a Web Broker Application (see page 2286)

3.2.5.1.4 Creating Internet Applications: Overview

Web server applications extend the functionality and capability of existing Web servers. A Web server application receives HTTP request messages from the Web server, performs any actions requested in those messages, and formulates responses that it passes back to the Web server. Many operations that you can perform with an ordinary application can be incorporated into a Web server application.

The IDE provides two different architectures for developing Web server applications: Web Broker and WebSnap. Although these two architectures are different, WebSnap and Web Broker have many common elements. The WebSnap architecture acts as a superset of Web Broker. It provides additional components and new features like the Preview tab, which allows the content of a page to be displayed without the developer having to run the application. Applications developed with WebSnap can include Web Broker components, whereas applications developed with Web Broker cannot include WebSnap components.

3.2.5.1.5 Terminology and standards

Topics

Name	Description
HTTP Request Header Information (see page 2252)	HTTP request messages contain many headers that describe information about the client, the target of the request, the way the request should be handled, and any content sent with the request. Each header is identified by a name, such as "Host" followed by a string value. For example, consider the following HTTP request:
Parts of a Uniform Resource Locator (see page 2253)	The Uniform Resource Locator (URL) is a complete description of the location of a resource that is available over the net. It is composed of several parts that may be accessed by an application. These parts are illustrated in the following figure:  The first portion (not technically part of the URL) identifies the protocol (http). This portion can specify other protocols such as https (secure http), ftp, and so on. The Host portion identifies the machine that runs the Web server and Web server application. Although it is not shown in the preceding picture, this portion can override the port... more (see page 2253)
Terminology and Standards (see page 2253)	Many of the protocols that control activity on the Internet are defined in Request for Comment (RFC) documents that are created, updated, and maintained by the Internet Engineering Task Force (IETF), the protocol engineering and development arm of the Internet. There are several important RFCs that you will find useful when writing Internet applications: • RFC822, "Standard for the format of ARPA Internet text messages," describes the structure and content of message headers. • RFC1521, "MIME (Multipurpose Internet Mail Extensions) Part One: Mechanisms for Specifying and Describing the Format of Internet Message Bodies," describes the method used to encapsulate and transport multipart... more (see page 2253)

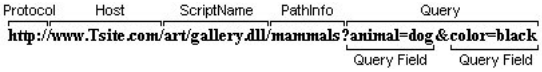
3.2.5.1.5.1 HTTP Request Header Information

HTTP request messages contain many headers that describe information about the client, the target of the request, the way the request should be handled, and any content sent with the request. Each header is identified by a name, such as "Host" followed by a string value. For example, consider the following HTTP request:

```
GET /art/gallery.dll/animals?animal=dog&color=black HTTP/1.0
Connection: Keep-Alive
User-Agent: Mozilla/3.0b4Gold (WinNT; I)
Host: www.TSite.com:1024
Accept: image/gif, image/x-xbitmap, image/jpeg, image/pjpeg, */*
```

The first line identifies the request as a GET. A GET request message asks the Web server application to return the content associated with the URI that follows the word GET (in this case /art/gallery.dll/animals?animal=doc&color=black). The last part of the first line indicates that the client is using the HTTP 1.0 standard.

The second line is the Connection header, and indicates that the connection should not be closed once the request is serviced. The third line is the User-Agent header, and provides information about the program generating the request. The next line is the Host header, and provides the Host name and port on the server that is contacted to form the connection. The final line is the Accept header, which lists the media types the client can accept as valid responses.



See Also

HTTP Server Activity (see page 2248)

Parts of a Uniform Resource Locator (see page 2253)

3.2.5.1.5.2 Parts of a Uniform Resource Locator

The Uniform Resource Locator (URL) is a complete description of the location of a resource that is available over the net. It is composed of several parts that may be accessed by an application. These parts are illustrated in the following figure:

The first portion (not technically part of the URL) identifies the protocol (http). This portion can specify other protocols such as https (secure http), ftp, and so on.

The Host portion identifies the machine that runs the Web server and Web server application. Although it is not shown in the preceding picture, this portion can override the port that receives messages. Usually, there is no need to specify a port, because the port number is implied by the protocol.

The ScriptName portion specifies the name of the Web server application. This is the application to which the Web server passes messages.

Following the script name is the pathinfo. This identifies the destination of the message within the Web server application. Path info values may refer to directories on the host machine, the names of components that respond to specific messages, or any other mechanism the Web server application uses to divide the processing of incoming messages.

The Query portion contains a set a named values. These values and their names are defined by the Web server application.

URI vs. URL

The URL is a subset of the Uniform Resource Identifier (URI) defined in the HTTP standard, RFC1945. Web server applications frequently produce content from many sources where the final result does not reside in a particular location, but is created as necessary. URIs can describe resources that are not location-specific.

See Also

Server Activity (see page 2248)

Request Header Information (see page 2252)

3.2.5.1.5.3 Terminology and Standards

Many of the protocols that control activity on the Internet are defined in Request for Comment (RFC) documents that are created, updated, and maintained by the Internet Engineering Task Force (IETF), the protocol engineering and development arm of the Internet. There are several important RFCs that you will find useful when writing Internet applications:

- RFC822, "Standard for the format of ARPA Internet text messages," describes the structure and content of message headers.
- RFC1521, "MIME (Multipurpose Internet Mail Extensions) Part One: Mechanisms for Specifying and Describing the Format of Internet Message Bodies," describes the method used to encapsulate and transport multipart and multiformat messages.
- RFC1945, "Hypertext Transfer Protocol—HTTP/1.0," describes a transfer mechanism used to distribute collaborative hypermedia documents.

The IETF maintains a library of the RFCs on their Web site, www.ietf.cnri.reston.va.us

These documents include, among other information, details about

- Parts of a Uniform Resource Locator (see page 2253)
- HTTP request header information (see page 2252)
- HTTP server activity (see page 2248)

3.2.5.2 Using IntraWeb (VCL for the Web)

For more documentation on VCL for the Web, go to http://www.atozed.com/intraweb/docs/.

Topics

Name	Description
Getting started with IntraWeb (see page 2254)	This tutorial demonstrates how to use IntraWeb. For more documentation on VCL for the Web, go to http://www.atozed.com/intraweb/docs/.
Using IntraWeb Components (see page 2258)	One of the advantages of IntraWeb is that it uses the same kinds of tools and techniques as regular VCL development. You can build your user interface by dropping components on forms, like you would any other application. There are a number of important differences that you must keep in mind, however. The forms and components used in IntraWeb user interfaces are not the same ones used in non-Web GUI applications. When you create a form or use a component, be sure to use an IntraWeb version instead of a VCL version. Many VCL components have IntraWeb counterparts. Generally, the... more (see page 2258)
Creating Web Server Applications Using IntraWeb (see page 2259)	IntraWeb is a tool which simplifies Web server application development. You can use IntraWeb to build Web server applications exactly the same way you would build traditional GUI applications, using forms. You can write all of your business logic in the Delphi language; IntraWeb will automatically convert program elements to script or HTML when necessary.
Using IntraWeb with Web Broker and WebSnap (see page 2260)	IntraWeb is a powerful tool for developing Web server applications all by itself. Still, there are some things it can't do alone, like create CGI applications. For CGI, you need Web Broker or WebSnap. Also, you may have existing Web Broker and WebSnap applications that you want to extend but not rewrite. You can still take advantage of IntraWeb's design tools by using IntraWeb forms and components in Web Broker or WebSnap projects. You can use IntraWeb to create individual pages instead of entire applications.

3.2.5.2.1 Getting started with IntraWeb

This tutorial demonstrates how to use IntraWeb. For more documentation on VCL for the Web, go to http://www.atozed.com/intraweb/docs/.

Topics

Name	Description
Getting Started with IntraWeb (see page 2255)	If you have experience writing GUI applications using Borland's rapid application development tools, then you already have the basic skills you need to start building applications with IntraWeb. The basic design method for the user interface is the same for IntraWeb and regular GUI applications: find the components you need on the **Tool palette** and drop them on a form. Unlike WebSnap's page modules, the appearance of the form mirrors the appearance of the page. The IntraWeb forms and components are distinct from their VCL counterparts, but they are named and arranged similarly. For example, let's say you... more (see page 2255)
Creating a New VCL for the Web Application (see page 2255)	The first step in the process of creating the demo program is to create a new VCL for the Web project. The project will be a stand alone application, but you can convert it to ISAPI/NSAPI or Apache later by changing two lines of code.
Editing the Main Form (see page 2256)	You are now ready to edit the main form to create the Web user interface for your application. For information on creating a new IntraWeb Application, see Creating a New IntraWeb Application (see page 2255).
Writing an Event Handler for the Button (see page 2256)	The form does not yet perform any actions when the user clicks the OK button. For information on editing the main form, see Editing the Main Form (see page 2256).
Running the Completed Application (see page 2257)	You can now test the IntraWeb application. For information on writing the event handler, see Writing an Event Handler for the Button (see page 2256).

Changing VCL for the Web application type (see page 2257)	If you have created a VCL for the Web application and wish to change it to ISAPI/NSAPI or Apache plugins, you can do it with a few simple changes to your code. It is, however, recommended that you start with a standalone application, to ease debugging, and later convert the application to an extension.

3.2.5.2.1.1 Getting Started with IntraWeb

If you have experience writing GUI applications using Borland's rapid application development tools, then you already have the basic skills you need to start building applications with IntraWeb. The basic design method for the user interface is the same for IntraWeb and regular GUI applications: find the components you need on the **Tool palette** and drop them on a form. Unlike WebSnap's page modules, the appearance of the form mirrors the appearance of the page. The IntraWeb forms and components are distinct from their VCL counterparts, but they are named and arranged similarly.

For example, let's say you want to add a button to a form. In an ordinary VCL application, you would find the Button component on the Standard **Tool palette** category and drop it on your form in an appropriate location. In the compiled application, the button appears where you placed it. For an IntraWeb application, the only difference is that you use the IWButton component on the IW Standard category. Even the icons for the two different button components look almost identical. The only difference is an "IW" in the top right corner of the IntraWeb button icon.

Follow the four step tutorial, below, to see how easy it is to build an IntraWeb application. The application you develop in the tutorial asks the user for some input and displays the input in a popup window. The tutorial uses IntraWeb's standalone mode, so the application you create will run without a commercial Web server.

For more documentation on VCL for the Web, go to http://www.atozed.com/intraweb/docs/.

The tutorial includes the following steps:

1. Creating a new IntraWeb application (see page 2255).
2. Editing the main form (see page 2256).
3. Writing an event handler for the button (see page 2256).
4. Running the completed application (see page 2257).

3.2.5.2.1.2 Creating a New VCL for the Web Application

The first step in the process of creating the demo program is to create a new VCL for the Web project. The project will be a stand alone application, but you can convert it to ISAPI/NSAPI or Apache later by changing two lines of code.

To create the new project:

1. Using an external tool (such as Microsoft Windows Explorer), create a directory named Hello in your Projects directory. This is where the project files will be stored. VCL for the Web will set the new project's name to match that of the directory.
2. Choose **File** ▸ **New** ▸ **Other**, then select **VCL for the Web** under either C++Builder Projects or Delphi Projects.
3. Select the **VCL for the Web Application Wizard** and click OK.
4. Select **File** ▸ **Save As** and locate your new Hello directory in the dialog box. Then click OK.

You have just created your VCL for the Web application in the Hello directory. All of its source code files have already been saved. You are now ready to edit the main form to create the Web user interface for your application.

See Also

Changing VCL for the Web application type (see page 2257)

Editing the Main Form (see page 2256)

3.2.5.2.1.3 Editing the Main Form

You are now ready to edit the main form to create the Web user interface for your application.

For information on creating a new IntraWeb Application, see Creating a New IntraWeb Application (see page 2255).

To create the Web user interface for your application:

1. Choose **File** ▸ **Open**, then select IWUnit1.pas and click OK. The main form window (named formMain) should appear in the IDE.
2. Click on the main form window. In the **Object Inspector**, change the form's *Title* property to "What is your name?" This question will appear in the title bar of the Web browser when you run the application and view the page corresponding to the main form.
3. Drop an IWLabel component (found on the IW Standard tab of the **Tool palette**) onto the form. In the **Object Inspector**, change the *Caption* property to "What is your name?" That question should now appear on the form.
4. Drop an IWEdit component onto the form underneath the IWLabel component. Use the **Object Inspector** to make the following changes:

- Empty the contents of the Text property.
- Set the *Name* property to editName.

5. Drop an IWButton component on the form underneath the IWEdit component. Set its *Caption* property to OK. Your form should look similar to this one:

You might want to save all your files before continuing.

For information about writing an event handler for the button, see Writing an Event Handler for the Button (see page 2256).

3.2.5.2.1.4 Writing an Event Handler for the Button

The form does not yet perform any actions when the user clicks the OK button.

For information on editing the main form, see Editing the Main Form (see page 2256).

You will now write an event handler that will display a greeting when the user clicks OK.

1. Double-click the OK button on the form. An empty event handler is created in the editor window, like the one shown here:

```
procedure TformMain.IWButton1Click(Sender: TObject);
begin

end;
```

2. Using the editor, add code to the event handler so it looks like the following:

```
procedure TformMain.IWButton1Click(Sender: TObject);
var s: string;
begin
   s := editName.Text;
   if Length(s) = 0 then
      WebApplication.ShowMessage("Please enter your name.")
   else
   begin
      WebApplication.ShowMessage("Hello, " + s +"!");
      editName.Text := "";
```

```
    end;
end;
```

For information about running the completed application, see Running the Completed Application (see page 2257).

3.2.5.2.1.5 Running the Completed Application

You can now test the IntraWeb application.

For information on writing the event handler, see Writing an Event Handler for the Button (see page 2256).

To test the IntraWeb application:

1. Select **Run** ▸ **Run**. The IntraWeb Application Server (shown below) will appear.

2. In the IntraWeb Application Server, select **Run** ▸ **Execute**. Your Web server application will appear in your default Web browser window. For example, here are the results in a Netscape 6 window:

3. Assume your name is World. Type World in the edit box and click the OK button. A modal dialog box will appear:

When you are finished using your application, you can terminate it by closing the browser window and then closing the IntraWeb Application Server.

3.2.5.2.1.6 Changing VCL for the Web application type

If you have created a VCL for the Web application and wish to change it to ISAPI/NSAPI or Apache plugins, you can do it with a few simple changes to your code.

It is, however, recommended that you start with a standalone application, to ease debugging, and later convert the application to an extension.

To change your standalone application to ISAPI/NSAPI:

1. Open the project source file by selecting **Project** ▸ **View Source**.

2. In the project source file, change the application type from **program** to **library**:
3. In the **uses** clause, replace the **Forms** and **IWMain** units with **ISAPIApp** and **IWInitISAPI**. If you want to use ISAPIThreadPool, include the **ISAPIThreadPool** unit in the **uses** clause.
4. Add the following **exports** section before the program entry point:

```
exports
  GetExtensionVersion,
  HttpExtensionProc,
  TerminateExtension;
```

5. Replace the contents of **begin** ... **end** block with:

```
begin
  IWRun;
end.
```

When you are done the project source file should look like this:

```
library Project1;

uses
  ISAPIApp,
  IWInitISAPI,
  ISAPIThreadPool,
  Unit1 in 'Unit1.pas' {IWForm1: TIWAppForm},
  ServerController in 'ServerController.pas' {IWServerController: TIWServerControllerBase},
  UserSessionUnit in 'UserSessionUnit.pas' {IWUserSession: TIWUserSessionBase};

{$R *.RES}

exports
  GetExtensionVersion,
  HttpExtensionProc,
  TerminateExtension;

begin
  IWRun;
end.
```

To change your standalone application to a service application:

1. Open the project source file by selecting **Project** ▸ **View Source**.
2. In the **uses** clause, replace the **Forms** and **IWMain** units with **IWInitService**.
3. Replace the contents of the **begin** ... **end** block with:

```
begin
  IWRun;
end.
```

Creating a New VCL for the Web Application (see page 2255)

3.2.5.2.2 Using IntraWeb Components

One of the advantages of IntraWeb is that it uses the same kinds of tools and techniques as regular VCL development. You can build your user interface by dropping components on forms, like you would any other application. There are a number of important differences that you must keep in mind, however. The forms and components used in IntraWeb user interfaces are not the same ones used in non-Web GUI applications. When you create a form or use a component, be sure to use an IntraWeb version instead of a VCL version.

Many VCL components have IntraWeb counterparts. Generally, the IntraWeb components have the same name as their VCL

counterparts, with the letters "IW" prefixed to the name. For example, IWCheckBox is the IntraWeb equivalent of CheckBox. (The name used in source code starts with the letter T, of course, like TIWCheckBox.) On the **Tool palette**, the icons for IntraWeb components are nearly identical to their VCL counterparts, making it easier to find the IntraWeb components you need.

The following table lists VCL components and their IntraWeb counterparts. For more information on these components and how to use them, refer to the IntraWeb help files and other IntraWeb documentation.

VCL and IntraWeb components

VCL component	IntraWeb equivalent	Tool palette category for IntraWeb component
Button	IWButton	IW Standard
CheckBox	IWCheckBox	IW Standard
ComboBox	IWComboBox	IW Standard
DBCheckBox	IWDBCheckBox	IW Data
DBComboBox	IWDBComboBox	IW Data
DBEdit	IWDBEdit	IW Data
DBGrid	IWDBGrid	IW Data
DBImage	IWDBImage	IW Data
DBLabel	IWDBLabel	IW Data
DBListBox	IWDBListBox	IW Data
DBLookupComboBox	IWDBLookupComboBox	IW Data
DBLookupListBox	IWDBLookupListBox	IW Data
DBMemo	IWDBMemo	IW Data
DBNavigator	IWDBNavigator	IW Data
DBText	IWDBText	IW Data
Edit	IWEdit	IW Standard
Image	IWImage or IWImageFile	IW Standard
Label	IWLabel	IW Standard
ListBox	IWListBox	IW Standard
Memo	IWMemo	IW Standard
RadioGroup	IWRadioGroup	IW Standard
Timer	IWTimer	IW Standard
TreeView	IWTreeView	IW Standard

3.2.5.2.3 Creating Web Server Applications Using IntraWeb

IntraWeb is a tool which simplifies Web server application development. You can use IntraWeb to build Web server applications exactly the same way you would build traditional GUI applications, using forms. You can write all of your business logic in the Delphi language; IntraWeb will automatically convert program elements to script or HTML when necessary.

You can use IntraWeb in any of the following modes:

1. **Standalone mode**. IntraWeb uses its own application object type to handle program execution. The application isn't deployed on a commercial server; instead, IntraWeb's own Application Server is used for application deployment.

2. **Application Mode**. The application object is provided by IntraWeb. The application is deployed on a commercial server.
3. **Page mode**. The application object is provided by Web Broker or WebSnap. IntraWeb is used to develop pages. The application is deployed on a commercial server.

IntraWeb applications can be targeted to any of the following server types:

- ISAPI/NSAPI
- Apache versions 1 and 2
- CGI (page mode only)
- Windows services

IntraWeb offers a wide range of browser compatibility. IntraWeb applications automatically detect the user's browser type and generate HTML and script most appropriate for that browser. IntraWeb supports Internet Explorer versions 4 through 6, Netscape 4 and 6, and Mozilla.

For more information, see: http://www.atozed.com/IntraWeb/index.en.aspx.

3.2.5.2.4 Using IntraWeb with Web Broker and WebSnap

IntraWeb is a powerful tool for developing Web server applications all by itself. Still, there are some things it can't do alone, like create CGI applications. For CGI, you need Web Broker or WebSnap. Also, you may have existing Web Broker and WebSnap applications that you want to extend but not rewrite. You can still take advantage of IntraWeb's design tools by using IntraWeb forms and components in Web Broker or WebSnap projects. You can use IntraWeb to create individual pages instead of entire applications.

To create Web pages using IntraWeb tools, use the following steps:

1. Create or open a Web Broker or WebSnap application, and drop a WebDispatcher component on your Web module (Web Broker) or Web application module (WebSnap). The WebDispatcher component is on the Internet tab of the **Tool palette**.
2. Drop an IWModuleController component on your Web module (Web Broker) or Web application module (WebSnap). IWModuleController is on the IW Control category of the **Tool palette**.
3. In WebSnap applications, create a new Web page module if necessary. In the New WebSnap Page dialog, uncheck the New File box in the HTML section before continuing.

   Note: If you create a page module with the New File box checked, you can change the result later. Open the page module's unit file in the editor. Next, change '.html' to an empty string ('') in the WebRequestHandler.AddWebModuleFactory call at the bottom of the unit.

4. Remove any existing page producer components from your Web module (Web Broker) or Web page module (WebSnap).
5. Drop an IWPageProducer component on your Web module or Web page module.
6. Select **File** ▶ **New** ▶ **Other** ▶ **IntraWeb** ▶ **Page Form** to create a new IntraWeb page form.
7. Add an *OnGetForm* event handler by double-clicking the IWPageProducer component on your Web module or Web page module. A new method will appear in the editor window.
8. Connect the IntraWeb form to the Web module or Web page module by adding a line of code to your *OnGetForm* event handler. The code line should be similar to, if not identical to, the following:

```
VForm := TformMain.Create(AWebApplication);
VForm = TformMain->Create(AWebApplication);
```

If necessary, change *TformMain* to the name of your IntraWeb form class. To find the form class name, click on the form. Its name appears next to the form window name in the **Object Inspector**.

9. In the unit file where you changed the event handler, add IWApplication and IWPageForm to the **uses** clause. Also, add the unit containing your form.

3.2.5.3 Using Web Broker

Topics

Name	Description
Generating the content of response messages (see page 2261)	
Using Web Broker (see page 2272)	Web Broker components (located on the Internet tab of the **Tool palette**) enable you to create event handlers that are associated with a specific Uniform Resource Identifier (URI). When processing is complete, you can programmatically construct HTML or XML documents and transfer them to the client. You can use Web Broker components for cross-platform application development. Frequently, the content of Web pages is drawn from databases. You can use Internet components to automatically manage connections to databases, allowing a single DLL to handle numerous simultaneous, thread-safe database connections. The following sections in this series explain how you use the... more (see page 2272)
The structure of a Web Broker application (see page 2272)	
Creating Web Server Applications with Web Broker (see page 2287)	Web Broker components (located on the Internet tab of the **Tool palette**) enable you to create event handlers that are associated with a specific Uniform Resource Identifier (URI). When processing is complete, you can programmatically construct HTML or XML documents and transfer them to the client. You can use Web Broker components for cross-platform application development.

3.2.5.3.1 Generating the content of response messages

Topics

Name	Description
Using database information in responses (see page 2262)	
Chaining Page Producers Together (see page 2268)	The replacement text from an OnHTMLTag event handler need not be the final HTML sequence you want to use in the HTTP response message. You may want to use several page producers, where the output from one page producer is the input for the next. The simplest way is to chain the page producers together is to associate each page producer with a separate action item, where all action items have the same *PathInfo* and *MethodType*. The first action item sets the content of the Web response message from its content producer, but its *OnAction* event handler makes sure... more (see page 2268)
Converting HTML-transparent Tags (see page 2269)	The page producer converts the HTML template when you call one of its *Content* methods. When the *Content* method encounters an HTML-transparent tag, it triggers the OnHTMLTag event. You must write an event handler to determine the type of tag encountered, and to replace it with customized content. See Using page producers from an action item (see page 2270) for a simple example of converting HTML-transparent tags. If you do not create an *OnHTMLTag* event handler for the page producer, HTML-transparent tags are replaced with an empty string.
Generating the Content of Response Messages (see page 2269)	Web Broker provides a number of objects to assist your action items in producing content for HTTP response messages. You can use these objects to generate strings of HTML commands that are saved in a file or sent directly back to the Web client. You can write your own content producers, deriving them from TCustomContentProducer or one of its descendants. *TCustomContentProducer* provides a generic interface for creating any MIME type as the content of an HTTP response message. Its descendants include page producers and table producers: • Page producers scan HTML documents for special tags that they replace with customized HTML... more (see page 2269)
HTML Templates (see page 2269)	An HTML template is a sequence of HTML commands and HTML-transparent tags. An HTML-transparent tag has the form

Specifying the HTML Template (see page 2270)	Page producers provide you with many choices in how to specify the HTML template. You can set the HTMLFile property to the name of a file that contains the HTML template. You can set the HTMLDoc property to a TStrings object that contains the HTML template. If you use either the *HTMLFile* property or the *HTMLDoc* property to specify the template, you can generate the converted HTML commands by calling the Content method. In addition, you can call the ContentFromString method to directly convert an HTML template that is a single string which is passed in as a parameter. You... more (see page 2270)
Using Page Producer Components (see page 2270)	Page producers (TPageProducer and its descendants) take an HTML template (see page 2269) and convert it by replacing special HTML-transparent tags with customized HTML code. You can store a set of standard response templates that are filled in by page producers when you need to generate the response to an HTTP request message. You can chain page producers together (see page 2268) to iteratively build up an HTML document by successive refinement of the HTML-transparent tags.
Using Page Producers from an Action Item (see page 2270)	A typical use of a page producer component uses the *HTMLFile* property to specify a file containing an HTML template. The *OnAction* event handler calls the *Content* method to convert the template into a final HTML sequence:
Using Predefined HTML-transparent Tag Names (see page 2271)	While you can create your own HTML-transparent tags to represent any kind of information processed by your page producer, there are several predefined tag names associated with values of the TTag data type. These predefined tag names correspond to HTML commands that are likely to vary over response messages. They are listed in the following table:

3.2.5.3.1.1 Using database information in responses

Topics

Name	Description
Adding a Session to the Web Module (see page 2264)	Console CGI applications are launched in response to HTTP request messages. When working with databases in these types of applications, you can use the default session to manage your database connections, because each request message has its own instance of the application. Each instance of the application has its own distinct, default session. When writing an ISAPI application or an NSAPI application, however, each request message is handled in a separate thread of a single application instance. To prevent the database connections from different threads from interfering with each other, you must give each thread its own session. Each request... more (see page 2264)
Embedding Tables in HTML Documents (see page 2264)	You can embed the HTML table that represents your dataset in a larger document by using the Header and Footer properties of the table producer. Use *Header* to specify everything that comes before the table, and *Footer* to specify everything that comes after the table. You may want to use another content producer (such as a page producer) to create the values for the *Header* and *Footer* properties. If you embed your table in a larger document, you may want to add a caption to the table. Use the Caption and CaptionAlignment properties to give your table a caption.
Representing a Dataset in HTML (see page 2265)	Specialized Content producer components on the Internet palette page supply HTML commands based on the records of a dataset. There are two types of data-aware content producers: • The dataset page producer (see page 2266), which formats the fields of a dataset into the text of an HTML document. • Table producers (see page 2267), which format the records of a dataset as an HTML table.
Specifying the Columns (see page 2265)	If you know the dataset for the table at design time, you can use the Columns editor to customize the columns' field bindings and display attributes. Select the table producer component, and right-click. From the context menu, choose the Columns editor. This lets you add, delete, or rearrange the columns in the table. You can set the field bindings and display properties of individual columns in the **Object Inspector** after selecting them in the Columns editor. If you are getting the name of the dataset from the HTTP request message, you can't bind the fields in the Columns editor at... more (see page 2265)

Specifying the Row Attributes (see page 2265)	Similar to the table attributes, you can specify the alignment and background color of cells in the rows of the table that display data. The RowAttributes property is a THTMLTableRowAttributes object. At design time, specify these properties using the **Object Inspector** by expanding the *RowAttributes* property. You can also specify these properties programmatically at runtime. You can also adjust the number of rows shown in the HTML table by setting the MaxRows property.
Specifying the Table Attributes (see page 2265)	Table producers use the THTMLTableAttributes object to describe the visual appearance of the HTML table that displays the records from the dataset. The *THTMLTableAttributes* object includes properties for the table's width and spacing within the HTML document, and for its background color, border thickness, cell padding, and cell spacing. These properties are all turned into options on the HTML <TABLE> tag created by the table producer. At design time, specify these properties using the **Object Inspector**. Select the table producer object in the **Object Inspector** and expand the TableAttributes property to access the display properties of the *THTMLTableAttributes* object.... more (see page 2265)
Using Dataset Page Producers (see page 2266)	Dataset page producers work like other page producer components: they convert a template that includes HTML-transparent tags into a final HTML representation. They include the special ability, however, of converting tags that have a tag name which matches the name of a field in a dataset into the current value of that field. For more information about using page producers in general, see Using page producer components (see page 2270). To use a dataset page producer, add a TDataSetPageProducer component to your Web module and set its DataSet property to the dataset whose field values should be displayed in the HTML content.... more (see page 2266)
Using Database Information in Responses (see page 2266)	The response to an HTTP request message may include information taken from a database. Specialized content producers on the Internet palette page can generate the HTML to represent the records from a database in an HTML table. To return database information in an HTTP response, you would typically • Add a session to the Web module (see page 2264) • Represent the database information in HTML (see page 2265) As an alternate approach, special components on the InternetExpress category of the **Tool palette** let you build Web servers that are part of a multi-tiered database application. See Building Web applications using InternetExpress (see page 1522) for details.
Using TDataSetTableProducer (see page 2266)	TDataSetTableProducer is a table producer that creates an HTML table for a dataset. Set the DataSet property of *TDataSetTableProducer* to specify the dataset that contains the records you want to display. You do not set the *DataSource* property, as you would for most data-aware objects in a conventional database application. This is because *TDataSetTableProducer* generates its own data source internally. You can set the value of *DataSet* at design time if your Web application always displays records from the same dataset. You must set the *DataSet* property at runtime if you are basing the dataset on the information in the... more (see page 2266)
Using TQueryTableProducer (see page 2267)	You can produce an HTML table to display the results of a query, where the parameters of the query come from the HTTP request message. Specify the TQuery object that uses those parameters as the Query property of a TQueryTableProducer component. If the request message is a GET request, the parameters of the query come from the *Query* fields of the URL that was given as the target of the HTTP request message. If the request message is a POST request, the parameters of the query come from the content of the request message. When you call the Content method... more (see page 2267)

Using Table Producers (see page 2267)	The Internet palette page includes two components that create an HTML table to represent the records of a dataset: • Dataset table producers (see page 2266), which format the fields of a dataset into the text of an HTML document. • Query table producers (see page 2267), which runs a query after setting parameters supplied by the request message and formats the resulting dataset as an HTML table. Using either of the two table producers, you can customize the appearance of a resulting HTML table by specifying properties for the table's color, border, separator thickness, and so on. To set the properties of a table producer... more (see page 2267)

3.2.5.3.1.1.1 Adding a Session to the Web Module

Console CGI applications are launched in response to HTTP request messages. When working with databases in these types of applications, you can use the default session to manage your database connections, because each request message has its own instance of the application. Each instance of the application has its own distinct, default session.

When writing an ISAPI application or an NSAPI application, however, each request message is handled in a separate thread of a single application instance. To prevent the database connections from different threads from interfering with each other, you must give each thread its own session.

Each request message in an ISAPI or NSAPI application spawns a new thread. The Web module (see page 2288) for that thread is generated dynamically at runtime. Add a *TSession* object to the Web module to handle the database connections for the thread that contains the Web module.

Separate instances of the Web module are generated for each thread at runtime. Each of those modules contains the session object. Each of those sessions must have a separate name, so that the threads that handle separate request messages do not interfere with each other's database connections. To cause the session objects in each module to dynamically generate unique names for themselves, set the AutoSessionName property of the session object. Each session object will dynamically generate a unique name for itself and set the SessionName property of all datasets in the module to refer to that unique name. This allows all interaction with the database for each request thread to proceed without interfering with any of the other request messages. For more information on sessions, see Managing database sessions (see page 1664).

Using Page Producer Components (see page 2270)

3.2.5.3.1.1.3 Representing a Dataset in HTML

Specialized Content producer components on the Internet palette page supply HTML commands based on the records of a dataset. There are two types of data-aware content producers:

- The dataset page producer (see page 2266), which formats the fields of a dataset into the text of an HTML document.
- Table producers (see page 2267), which format the records of a dataset as an HTML table.

See Also

Add a session to the Web module (see page 2264)

3.2.5.3.1.1.4 Specifying the Columns

If you know the dataset for the table at design time, you can use the Columns editor to customize the columns' field bindings and display attributes. Select the table producer component, and right-click. From the context menu, choose the Columns editor. This lets you add, delete, or rearrange the columns in the table. You can set the field bindings and display properties of individual columns in the **Object Inspector** after selecting them in the Columns editor.

If you are getting the name of the dataset from the HTTP request message, you can't bind the fields in the Columns editor at design time. However, you can still customize the columns programmatically at runtime, by setting up the appropriate THTMLTableColumn objects and using the methods of the Columns property to add them to the table. If you do not set up the *Columns property*, the table producer creates a default set of columns that match the fields of the dataset and specify no special display characteristics.

See Also

Specifying the Table Attributes (see page 2265)

Specifying the Row Attributes (see page 2265)

Embedding Tables in HTML Documents (see page 2264)

3.2.5.3.1.1.5 Specifying the Row Attributes

Similar to the table attributes, you can specify the alignment and background color of cells in the rows of the table that display data. The RowAttributes property is a THTMLTableRowAttributes object.

At design time, specify these properties using the **Object Inspector** by expanding the *RowAttributes* property. You can also specify these properties programmatically at runtime.

You can also adjust the number of rows shown in the HTML table by setting the MaxRows property.

Specifying the Table Attributes (see page 2265)

Specifying the Columns (see page 2265)

Embedding Tables in HTML Documents (see page 2264)

3.2.5.3.1.1.6 Specifying the Table Attributes

Table producers use the THTMLTableAttributes object to describe the visual appearance of the HTML table that displays the records from the dataset. The *THTMLTableAttributes* object includes properties for the table's width and spacing within the

HTML document, and for its background color, border thickness, cell padding, and cell spacing. These properties are all turned into options on the HTML <TABLE> tag created by the table producer.

At design time, specify these properties using the **Object Inspector**. Select the table producer object in the **Object Inspector** and expand the TableAttributes property to access the display properties of the *THTMLTableAttributes* object.

You can also specify these properties programmatically at runtime.

Specifying the Row Attributes (see page 2265)

Specifying the Columns (see page 2265)

Embedding Tables in HTML Documents (see page 2264)

3.2.5.3.1.1.7 Using Dataset Page Producers

Dataset page producers work like other page producer components: they convert a template that includes HTML-transparent tags into a final HTML representation. They include the special ability, however, of converting tags that have a tag name which matches the name of a field in a dataset into the current value of that field. For more information about using page producers in general, see Using page producer components (see page 2270).

To use a dataset page producer, add a TDataSetPageProducer component to your Web module and set its DataSet property to the dataset whose field values should be displayed in the HTML content. Create an HTML template that describes the output of your dataset page producer. For every field value you want to display, include a tag of the form

```
<#FieldName>
```

in the HTML template, where *FieldName* specifies the name of the field in the dataset whose value should be displayed.

When your application calls the *Content*, *ContentFromString*, or *ContentFromStream* method, the dataset page producer substitutes the current field values for the tags that represent fields.

Using Table Producers (see page 2267)

3.2.5.3.1.1.8 Using Database Information in Responses

The response to an HTTP request message may include information taken from a database. Specialized content producers on the Internet palette page can generate the HTML to represent the records from a database in an HTML table.

To return database information in an HTTP response, you would typically

- Add a session to the Web module (see page 2264)
- Represent the database information in HTML (see page 2265)

As an alternate approach, special components on the InternetExpress category of the **Tool palette** let you build Web servers that are part of a multi-tiered database application. See Building Web applications using InternetExpress (see page 1522) for details.

See Also

Using Page Producer Components (see page 2270)

3.2.5.3.1.1.9 Using TDataSetTableProducer

TDataSetTableProducer is a table producer that creates an HTML table for a dataset. Set the DataSet property of *TDataSetTableProducer* to specify the dataset that contains the records you want to display. You do not set the *DataSource* property, as you would for most data-aware objects in a conventional database application. This is because *TDataSetTableProducer* generates its own data source internally.

You can set the value of *DataSet* at design time if your Web application always displays records from the same dataset. You must set the *DataSet* property at runtime if you are basing the dataset on the information in the HTTP request message.

Specifying the Row Attributes (see page 2265)

Specifying the Columns (see page 2265)

Embedding Tables in HTML Documents (see page 2264)

Using TQueryTableProducer (see page 2267)

3.2.5.3.1.1.10 Using TQueryTableProducer

You can produce an HTML table to display the results of a query, where the parameters of the query come from the HTTP request message. Specify the TQuery object that uses those parameters as the Query property of a TQueryTableProducer component.

If the request message is a GET request, the parameters of the query come from the *Query* fields of the URL that was given as the target of the HTTP request message. If the request message is a POST request, the parameters of the query come from the content of the request message.

When you call the Content method of *TQueryTableProducer*, it runs the query, using the parameters it finds in the request object. It then formats an HTML table to display the records in the resulting dataset.

As with any table producer, you can customize the display properties or column bindings of the HTML table, or embed the table in a larger HTML document.

Specifying the Table Attributes (see page 2265)

Specifying the Row Attributes (see page 2265)

Specifying the Columns (see page 2265)

Embedding Tables in HTML Documents (see page 2264)

Using TDataSetTableProducer (see page 2266)

3.2.5.3.1.1.11 Using Table Producers

The Internet palette page includes two components that create an HTML table to represent the records of a dataset:

- Dataset table producers (see page 2266), which format the fields of a dataset into the text of an HTML document.
- Query table producers (see page 2267), which runs a query after setting parameters supplied by the request message and formats the resulting dataset as an HTML table.

Using either of the two table producers, you can customize the appearance of a resulting HTML table by specifying properties for the table's color, border, separator thickness, and so on. To set the properties of a table producer at design time, double-click the table producer component to display the Response Editor dialog.

- Specifying the table attributes (see page 2265)
- Specifying the row attributes (see page 2265)
- Specifying the columns (see page 2265)
- Embedding tables in HTML documents (see page 2264)

See Also

Using Dataset Page Producers (see page 2266)

3.2.5.3.1.2 Chaining Page Producers Together

The replacement text from an OnHTMLTag event handler need not be the final HTML sequence you want to use in the HTTP response message. You may want to use several page producers, where the output from one page producer is the input for the next.

The simplest way is to chain the page producers together is to associate each page producer with a separate action item, where all action items have the same *PathInfo* and *MethodType*. The first action item sets the content of the Web response message from its content producer, but its *OnAction* event handler makes sure the message is not considered handled. The next action item uses the ContentFromString method of its associated producer to manipulate the content of the Web response message, and so on. Action items after the first one use an *OnAction* event handler such as the following:

```
procedure WebModule1.Action2Action(Sender: TObject; Request: TWebRequest;
   Response: TWebResponse; var Handled: Boolean);
begin
  Response.Content := PageProducer2.ContentFromString(Response.Content);
end;
void __fastcall WebModule1::Action2Action(TObject *Sender,
   TWebRequest *Request, TWebResponse *Response, bool &Handled)
{
  Response->Content = PageProducer2->ContentFromString(Response->Content);
}
```

For example, consider an application that returns calendar pages in response to request messages that specify the month and year of the desired page. Each calendar page contains a picture, followed by the name and year of the month between small images of the previous month and next months, followed by the actual calendar. The resulting image looks something like this:

The general form of the calendar is stored in a template file. It looks like this:

```
<HTML>
<Head></HEAD>
<BODY>
<#MonthlyImage> <#TitleLine><#MainBody>
</BODY>
</HTML>
```

The *OnHTMLTag* event handler of the first page producer looks up the month and year from the request message. Using that information and the template file, it does the following:

- Replaces <#MonthlyImage> with <#Image Month=January Year=2000>.
- Replaces <#TitleLine> with <#Calendar Month=December Year=1999 Size=Small> January 2000 <#Calendar Month=February Year=2000 Size=Small>.
- Replaces <#MainBody> with <#Calendar Month=January Year=2000 Size=Large>.

The *OnHTMLTag* event handler of the next page producer uses the content produced by the first page producer, and replaces the <#Image Month=January Year=2000> tag with the appropriate HTML <IMG> tag. Yet another page producer resolves the

#Calendar tags with appropriate HTML tables.

See Also

HTML Templates (see page 2269)

Converting HTML-transparent Tags (see page 2269)

3.2.5.3.1.3 Converting HTML-transparent Tags

The page producer converts the HTML template when you call one of its *Content* methods. When the *Content* method encounters an HTML-transparent tag, it triggers the OnHTMLTag event. You must write an event handler to determine the type of tag encountered, and to replace it with customized content. See Using page producers from an action item (see page 2270) for a simple example of converting HTML-transparent tags.

If you do not create an *OnHTMLTag* event handler for the page producer, HTML-transparent tags are replaced with an empty string.

See Also

Using Predefined HTML-transparent Tag Names (see page 2271)

Specifying the HTML Template (see page 2270)

3.2.5.3.1.4 Generating the Content of Response Messages

Web Broker provides a number of objects to assist your action items in producing content for HTTP response messages. You can use these objects to generate strings of HTML commands that are saved in a file or sent directly back to the Web client. You can write your own content producers, deriving them from TCustomContentProducer or one of its descendants.

TCustomContentProducer provides a generic interface for creating any MIME type as the content of an HTTP response message. Its descendants include page producers and table producers:

- Page producers scan HTML documents for special tags that they replace with customized HTML code. They are described in Using page producer components (see page 2270).
- Table producers create HTML commands based on the information in a dataset. They are described in Using database information in responses (see page 2266).

See Also

Action Items (see page 2278)

The Web Dispatcher (see page 2287)

Creating HTTP Response Messages (see page 2283)

3.2.5.3.1.5 HTML Templates

An HTML template is a sequence of HTML commands and HTML-transparent tags. An HTML-transparent tag has the form

```
<#TagName Param1=Value1 Param2=Value2 ...>
```

The angle brackets (< and >) define the entire scope of the tag. A pound sign (#) immediately follows the opening angle bracket (<) with no spaces separating it from the angle bracket. The pound sign identifies the string to the page producer as an HTML-transparent tag. The tag name immediately follows the pound sign with no spaces separating it from the pound sign. The tag name can be any valid identifier and identifies the type of conversion the tag represents.

Following the tag name, the HTML-transparent tag can optionally include parameters that specify details of the conversion to be performed. Each parameter is of the form *ParamName=Value*, where there is no space between the parameter name, the equals

symbol (=) and the value. The parameters are separated by whitespace.

The angle brackets (< and >) make the tag transparent to HTML browsers that do not recognize the #TagName construct.

When working with HTML templates, you will

- Optionally, Use predefined HTML-transparent tag Names (see page 2271)
- Specify the HTML template (see page 2270)
- Convert HTML-transparent tags (see page 2269)

See Also

Chaining Page Producers Together (see page 2268)

3.2.5.3.1.6 Specifying the HTML Template

Page producers provide you with many choices in how to specify the HTML template. You can set the HTMLFile property to the name of a file that contains the HTML template. You can set the HTMLDoc property to a TStrings object that contains the HTML template. If you use either the *HTMLFile* property or the *HTMLDoc* property to specify the template, you can generate the converted HTML commands by calling the Content method.

In addition, you can call the ContentFromString method to directly convert an HTML template that is a single string which is passed in as a parameter. You can also call the ContentFromStream method to read the HTML template from a stream. Thus, for example, you could store all your HTML templates in a memo field in a database, and use the *ContentFromStream* method to obtain the converted HTML commands, reading the template directly from a TBlobStream object.

See Also

Using Predefined HTML-transparent Tag Names (see page 2271)

Converting HTML-transparent Tags (see page 2269)

3.2.5.3.1.7 Using Page Producer Components

Page producers (TPageProducer and its descendants) take an HTML template (see page 2269) and convert it by replacing special HTML-transparent tags with customized HTML code. You can store a set of standard response templates that are filled in by page producers when you need to generate the response to an HTTP request message. You can chain page producers together (see page 2268) to iteratively build up an HTML document by successive refinement of the HTML-transparent tags.

See Also

Using Database Information in Responses (see page 2266)

3.2.5.3.1.8 Using Page Producers from an Action Item

A typical use of a page producer component uses the *HTMLFile* property to specify a file containing an HTML template. The *OnAction* event handler calls the *Content* method to convert the template into a final HTML sequence:

```
procedure WebModule1.MyActionEventHandler(Sender: TObject; Request: TWebRequest;
   Response: TWebResponse; var Handled: Boolean);
begin
   PageProducer1.HTMLFile := 'Greeting.html';
   Response.Content := PageProducer1.Content;
end;
void __fastcall WebModule1::MyActionEventHandler(TObject *Sender,
   TWebRequest *Request, TWebResponse *Response, bool &Handled)
{
  PageProducer1->HTMLFile = "Greeting.html";
  Response->Content = PageProducer1->Content();
}
```

Greeting.html is a file that contains this HTML template:

```
<HTML>
<HEAD><TITLE>Our Brand New Web Site</TITLE></HEAD>
<BODY>
Hello <#UserName>!  Welcome to our Web site.
</BODY>
</HTML>
```

The *OnHTMLTag* event handler replaces the custom tag (<#UserName>) in the HTML during execution:

```
procedure WebModule1.PageProducer1HTMLTag(Sender : TObject;Tag: TTag;
   const TagString: string; TagParams: TStrings; var ReplaceText: string);
begin
   if CompareText(TagString,'UserName') = 0 then
      ReplaceText := TPageProducer(Sender).Dispatcher.Request.Content;
end;
void __fastcall WebModule1::HTMLTagHandler(TObject *Sender, TTag Tag,
   const AnsiString TagString, TStrings *TagParams, AnsiString &ReplaceText)
{
  if (CompareText(TagString,"UserName") == 0)
    ReplaceText = ((TPageProducer *)Sender)->Dispatcher->Request->Content;
}
```

If the content of the request message was the string *Mr. Ed*, the value of *Response.Content* would be

```
<HTML>
<HEAD><TITLE>Our Brand New Web Site</TITLE></HEAD>
<BODY>
Hello Mr. Ed!  Welcome to our Web site.
</BODY>
</HTML>
```

Note: This example uses an *OnAction* event handler to call the content producer and assign the content of the response message. You do not need to write an *OnAction* event handler if you assign the page producer's *HTMLFile* property at design time. In that case, you can simply assign *PageProducer1* as the value of the action item's *Producer* property to accomplish the same effect as the *OnAction* event handler above.

HTML Templates (see page 2269)

Responding to Request Messages with Action Items (see page 2280)

3.2.5.3.1.9 Using Predefined HTML-transparent Tag Names

While you can create your own HTML-transparent tags to represent any kind of information processed by your page producer, there are several predefined tag names associated with values of the TTag data type. These predefined tag names correspond to HTML commands that are likely to vary over response messages. They are listed in the following table:

Tag Name	TTag value	What the tag should be converted to
Link	*tgLink*	A hypertext link. The result is an HTML sequence beginning with an <A> tag and ending with an </A> tag.
Image	*tgImage*	A graphic image. The result is an HTML <IMG> tag.
Table	*tgTable*	An HTML table. The result is an HTML sequence beginning with a <TABLE> tag and ending with a </TABLE> tag.
ImageMap	*tgImageMap*	A graphic image with associated hot zones. The result is an HTML sequence beginning with a <MAP> tag and ending with a </MAP> tag.
Object	*tgObject*	An embedded ActiveX object. The result is an HTML sequence beginning with an <OBJECT> tag and ending with an </OBJECT> tag.

Embed	*tgEmbed*	A Netscape-compliant add-in DLL. The result is an HTML sequence beginning with an <EMBED> tag and ending with an </EMBED> tag.

Any other tag name is associated with tgCustom. The page producer supplies no built-in processing of the predefined tag names. They are simply provided to help applications organize the conversion process into many of the more common tasks.

Note: The predefined tag names are case insensitive.

3.2.5.3.2 Using Web Broker

Web Broker components (located on the Internet tab of the **Tool palette**) enable you to create event handlers that are associated with a specific Uniform Resource Identifier (URI). When processing is complete, you can programmatically construct HTML or XML documents and transfer them to the client. You can use Web Broker components for cross-platform application development.

Frequently, the content of Web pages is drawn from databases. You can use Internet components to automatically manage connections to databases, allowing a single DLL to handle numerous simultaneous, thread-safe database connections.

The following sections in this series explain how you use the Web Broker components to create a Web server application.

Topics

Name	Description
Accessing client request information (see page 2273)	
Adding Actions to the Dispatcher (see page 2277)	Open the action editor from the **Object Inspector** by clicking the ellipsis on the *Actions* property of the dispatcher. Action items (see page 2278) can be added to the dispatcher by clicking the Add button in the action editor. Add actions to the dispatcher to respond to different request methods or target URIs. You can set up your action items in a variety of ways. You can start with action items that preprocess requests, and end with a default action that checks whether the response is complete and either sends the response or returns an error code. Or, you can add a separate... more (see page 2277)
Action items (see page 2277)	
Dispatching Request Messages (see page 2281)	When the dispatcher receives the client request, it generates a BeforeDispatch event. This provides your application with a chance to preprocess the request message before it is seen by any of the action items (see page 2278). Next, the dispatcher iterates over its list of action items, looking for an entry that matches the PathInfo portion of the request message's target URL and that also provides the service specified as the method of the request message. It does this by comparing the PathInfo and MethodType properties of the *TWebRequest* object with the property of the same name on the action item. When... more (see page 2281)
Creating HTTP response messages (see page 2282)	

The Structure of a Web Broker Application (see page 2286)	When the Web application (see page 2288) receives an HTTP request message, it creates a TWebRequest object to represent the HTTP request message, and a TWebResponse object to represent the response that should be returned. The application then passes these objects to the Web dispatcher (either the Web module or a *TWebDispatcher* component). The Web dispatcher (see page 2287) controls the flow of the Web server application. The dispatcher maintains a collection of action items (*TWebActionItem*) that know how to handle certain types of HTTP request messages. The dispatcher identifies the appropriate action items or auto-dispatching components to handle the HTTP request message, and... more (see page 2286)
The Web dispatcher (see page 2287)	

3.2.5.3.3.1 Accessing client request information

Topics

Name	Description
Accessing Client Request Information (see page 2274)	When an HTTP request message is received by the Web server application, the headers of the client request are loaded into the properties of an object descended from *TWebRequest*. For example, in NSAPI and ISAPI applications, the request message is encapsulated by a TISAPIRequest object, and console CGI applications use TCGIRequest objects. The properties of the request object are read-only. You can use them to gather all of the information available in the client request, including • Request header information (see page 2274) • The content of the request message (see page 2276)
Properties That Contain Request Header Information (see page 2274)	Most properties in a request object contain information about the request that comes from the HTTP request header. Not every request supplies a value for every one of these properties. Also, some requests may include header fields that are not surfaced in a property of the request object, especially as the HTTP standard continues to evolve. To obtain the value of a request header field that is not surfaced as one of the properties of the request object, use the GetFieldByName method. The request header properties can be categorized by function: • Properties that identify the target (see page 2276) • Properties that describe the (see page 2275)... more (see page 2274)
Properties That Describe the Content (see page 2275)	Most requests do not include any content, as they are requests for information. However, some requests, such as POST requests, provide content that the Web server application is expected to use. The media type of the content is given in the ContentType property, and its length in the ContentLength property. If the content of the message was encoded (for example, for data compression), this information is in the ContentEncoding property. The name and version number of the application that produced the content is specified by the ContentVersion property. The Title property may also provide information about the content.
Properties That Describe the Expected Response (see page 2275)	The Accept property indicates the media types the Web client will accept as the content of the response message. The IfModifiedSince property specifies whether the client only wants information that has changed recently. The Cookie property includes state information (usually added previously by your application) that can modify the response.
Properties That Describe the Web Client (see page 2275)	The request includes several properties that provide information about where the request originated. These include everything from the e-mail address of the sender (the From property), to the URI where the message originated (the Referer or RemoteHost property). If the request contains any content, and that content does not arise from the same URI as the request, the source of the content is given by the DerivedFrom property. You can also determine the IP address of the client (the RemoteAddr property), and the name and version of the application that sent the request (the UserAgent property).
Properties That Identify the Purpose of the Request (see page 2275)	The Method property is a string describing what the request message is asking the server application to do. The HTTP 1.1 standard defines the following methods: ***Predefined tag names***

Properties That Identify the Target (see page 2276)	The full target of the request message is given by the URL property. Usually, this is a URL that can be broken down into the protocol (HTTP), Host (server system), ScriptName (server application), PathInfo (location on the host), and Query. Each of these pieces is surfaced in its own property. The protocol is always HTTP, and the *Host* and *ScriptName* identify the Web server application. The dispatcher uses the *PathInfo* portion when matching action items to request messages. The *Query* is used by some requests to specify the details of the requested information. Its value is also parsed for you... more (see page 2276)
The Content of HTTP Request Messages (see page 2276)	In addition to the header fields, some request messages include a content portion that the Web server application should process in some way. For example, a POST request might include information that should be added to a database accessed by the Web server application. The unprocessed value of the content is given by the Content property. If the content can be parsed into fields separated by ampersands (&), a parsed version is available in the ContentFields property.

3.2.5.3.3.1.1 Accessing Client Request Information

When an HTTP request message is received by the Web server application, the headers of the client request are loaded into the properties of an object descended from *TWebRequest*. For example, in NSAPI and ISAPI applications, the request message is encapsulated by a TISAPIRequest object, and console CGI applications use TCGIRequest objects.

The properties of the request object are read-only. You can use them to gather all of the information available in the client request, including

- Request header information (see page 2274)
- The content of the request message (see page 2276)

Generating the Content of Response Messages (see page 2269)

Types of Web Server Applications (see page 2249)

3.2.5.3.3.1.2 Properties That Contain Request Header Information

Most properties in a request object contain information about the request that comes from the HTTP request header. Not every request supplies a value for every one of these properties. Also, some requests may include header fields that are not surfaced in a property of the request object, especially as the HTTP standard continues to evolve. To obtain the value of a request header field that is not surfaced as one of the properties of the request object, use the GetFieldByName method.

The request header properties can be categorized by function:

- Properties that identify the target (see page 2276)
- Properties that describe the Web client (see page 2275)
- Properties that identify the purpose of the request (see page 2275)
- Properties that describe the expected response (see page 2275)
- Properties that describe the content (see page 2275)

See Also

The Content of HTTP Request Messages (see page 2276)

HTTP Request Header Information (see page 2252)

3.2.5.3.3.1.3 Properties That Describe the Content

Most requests do not include any content, as they are requests for information. However, some requests, such as POST requests, provide content that the Web server application is expected to use. The media type of the content is given in the ContentType property, and its length in the ContentLength property. If the content of the message was encoded (for example, for data compression), this information is in the ContentEncoding property. The name and version number of the application that produced the content is specified by the ContentVersion property. The Title property may also provide information about the content.

Properties That Identify the Purpose of the Request (see page 2275)

Properties That Describe the Expected Response (see page 2275)

The Content of HTTP Request Messages (see page 2276)

3.2.5.3.3.1.4 Properties That Describe the Expected Response

The Accept property indicates the media types the Web client will accept as the content of the response message. The IfModifiedSince property specifies whether the client only wants information that has changed recently. The Cookie property includes state information (usually added previously by your application) that can modify the response.

See Also

Properties That Identify the Target (see page 2276)

Properties That Describe the Web Client (see page 2275)

Properties That Identify the Purpose of the Request (see page 2275)

Properties That Describe the Content (see page 2275)

3.2.5.3.3.1.5 Properties That Describe the Web Client

The request includes several properties that provide information about where the request originated. These include everything from the e-mail address of the sender (the From property), to the URI where the message originated (the Referer or RemoteHost property). If the request contains any content, and that content does not arise from the same URI as the request, the source of the content is given by the DerivedFrom property. You can also determine the IP address of the client (the RemoteAddr property), and the name and version of the application that sent the request (the UserAgent property).

See Also

Properties That Identify the Target (see page 2276)

Properties That Identify the Purpose of the Request (see page 2275)

Properties That Describe the Expected Response (see page 2275)

Properties That Describe the Content (see page 2275)

3.2.5.3.3.1.6 Properties That Identify the Purpose of the Request

The Method property is a string describing what the request message is asking the server application to do. The HTTP 1.1 standard defines the following methods:

Predefined tag names

Value	What the message requests
OPTIONS	Information about available communication options.
GET	Information identified by the URL property.
HEAD	Header information from an equivalent GET message, without the content of the response.
POST	The server application to post the data included in the Content property, as appropriate.
PUT	The server application to replace the resource indicated by the URL property with the data included in the Content property.
DELETE	The server application to delete or hide the resource identified by the URL property.
TRACE	The server application to send a loop-back to confirm receipt of the request.

The *Method* property may indicate any other method that the Web client requests of the server.

The Web server application does not need to provide a response for every possible value of *Method*. The HTTP standard does require that it service both GET and HEAD requests, however.

The MethodType property indicates whether the value of *Method* is GET (mtGet), HEAD (mtHead), POST (mtPost), PUT (mtPut) or some other string (mtAny). The dispatcher matches the value of the *MethodType* property with the *MethodType* of each action item.

See Also

Properties That Identify the Target (see page 2276)

Properties That Describe the Web Client (see page 2275)

Properties That Describe the Expected Response (see page 2275)

Properties That Describe the Content (see page 2275)

3.2.5.3.3.1.7 Properties That Identify the Target

The full target of the request message is given by the URL property. Usually, this is a URL that can be broken down into the protocol (HTTP), Host (server system), ScriptName (server application), PathInfo (location on the host), and Query.

Each of these pieces is surfaced in its own property. The protocol is always HTTP, and the *Host* and *ScriptName* identify the Web server application. The dispatcher uses the *PathInfo* portion when matching action items to request messages. The *Query* is used by some requests to specify the details of the requested information. Its value is also parsed for you as the QueryFields property.

Parts of a Uniform Resource Locator (see page 2253)

3.2.5.3.3.1.8 The Content of HTTP Request Messages

In addition to the header fields, some request messages include a content portion that the Web server application should process in some way. For example, a POST request might include information that should be added to a database accessed by the Web server application.

The unprocessed value of the content is given by the Content property. If the content can be parsed into fields separated by ampersands (&), a parsed version is available in the ContentFields property.

See Also

Properties That Contain Request Header Information (see page 2274)

Composing Client Requests (see page 2248)

3.2.5.3.3.2 Adding Actions to the Dispatcher

Open the action editor from the **Object Inspector** by clicking the ellipsis on the *Actions* property of the dispatcher. Action items (see page 2278) can be added to the dispatcher by clicking the Add button in the action editor.

Add actions to the dispatcher to respond to different request methods or target URIs. You can set up your action items in a variety of ways. You can start with action items that preprocess requests, and end with a default action that checks whether the response is complete and either sends the response or returns an error code. Or, you can add a separate action item for every type of request, where each action item completely handles the request.

Name	Description
Action Items (see page 2278)	Each action item (TWebActionItem) performs a specific task in response to a given type of request message. Action items can completely respond to a request or perform part of the response and allow other action items to complete the job. Action items can send the HTTP response message for the request, or simply set up part of the response for other action items to complete. If a response is completed by the action items but not sent, the Web server application sends the response message. Set up action items for your Web server application by • Adding actions to the dispatcher (see page 2277)... more (see page 2278)
Choosing a Default Action Item (see page 2278)	Only one of the action items can be the default action item. The default action item is selected by setting its Default property to *True*. When the *Default* property of an action item is set to *True*, the *Default* property for the previous default action item (if any) is set to *False*. When the dispatcher searches its list of action items to choose one to handle a request, it stores the name of the default action item. If the request has not been fully handled when the dispatcher reaches the end of its list of action items,... more (see page 2278)
Determining When Action Items Fire (see page 2279)	Most properties of the action item determine when the dispatcher selects it to handle an HTTP request message. To set the properties of an action item, you must first bring up the action editor: select the *Actions* property of the dispatcher in the **Object Inspector** and click on the ellipsis. When an action is selected in the action editor, its properties can be modified in the **Object Inspector**. The action item includes properties that specify • The target URL (see page 2281) • The request method type (see page 2280) Other properties that influence when the dispatcher fires an action item are described in • Enabling and disabling (see page 2279)... more (see page 2279)

Enabling and Disabling Action Items (see page 2279)	Each action item has an Enabled property that can be used to enable or disable that action item. By setting *Enabled* to *False*, you disable the action item so that it is not considered by the dispatcher when it looks for an action item to handle a request. A BeforeDispatch event handler can control which action items should process a request by changing the *Enabled* property of the action items before the dispatcher begins matching them to the request message. **Warning:** Changing the *Enabled* property of an action during execution may cause unexpected results for subsequent requests. If the... more (see page 2279)
Responding to Request Messages with Action Items (see page 2280)	The real work of the Web server application is performed by action items when they execute. When the Web dispatcher fires an action item, that action item can respond to the current request message in two ways: • If the action item has an associated producer component as the value of its Producer property, that producer automatically assigns the Content of the response message using its Content method. The Internet page of the **Tool palette** includes a number of content producer components that can help construct an HTML page for the content of the response message. • After the producer has assigned... more (see page 2280)
The Request Method Type (see page 2280)	The MethodType property of an action item indicates what type of request messages it can process. The dispatcher compares the *MethodType* property of an action item to the *MethodType* of the request message. *MethodType* can take one of the following values: ***MethodType values***
The Target URL (see page 2281)	The dispatcher compares the PathInfo property of an action item to the *PathInfo* of the request message. The value of this property should be the path information portion of the URL for all requests that the action item is prepared to handle. For example, given this URL,

3.2.5.3.3.3.1 Action Items

Each action item (TWebActionItem) performs a specific task in response to a given type of request message.

Action items can completely respond to a request or perform part of the response and allow other action items to complete the job. Action items can send the HTTP response message for the request, or simply set up part of the response for other action items to complete. If a response is completed by the action items but not sent, the Web server application sends the response message.

Set up action items for your Web server application by

- Adding actions to the dispatcher (see page 2277)
- Determining when action items fire (see page 2279)
- Responding to request messages with action items (see page 2280)

See Also

The Web Dispatcher (see page 2287)

Creating HTTP Response Messages (see page 2283)

Generating the Content of Response Messages (see page 2269)

3.2.5.3.3.3.2 Choosing a Default Action Item

Only one of the action items can be the default action item. The default action item is selected by setting its Default property to *True*. When the *Default* property of an action item is set to *True*, the *Default* property for the previous default action item (if any) is set to *False*.

When the dispatcher searches its list of action items to choose one to handle a request, it stores the name of the default action item. If the request has not been fully handled when the dispatcher reaches the end of its list of action items, it executes the default action item.

The dispatcher does not check the *PathInfo* or *MethodType* of the default action item. The dispatcher does not even check the Enabled property of the default action item. Thus, you can make sure the default action item is only called at the very end by setting its Enabled property to *False*.

The default action item should be prepared to handle any request that is encountered, even if it is only to return an error code indicating an invalid URI or *MethodType*. If the default action item does not handle the request, no response is sent to the Web client.

Warning: Changing the *Default* property of an action during execution may cause unexpected results for the current request. If the *Default* property of an action that has already been triggered is set to *True*, that action will not be reevaluated and the dispatcher will not trigger that action when it reaches the end of the action list.

The Target URL (see page 2281)

The Request Method Type (see page 2280)

Enabling and Disabling Action Items (see page 2279)

Dispatching Request Messages (see page 2281)

3.2.5.3.3.3.3 Determining When Action Items Fire

Most properties of the action item determine when the dispatcher selects it to handle an HTTP request message. To set the properties of an action item, you must first bring up the action editor: select the *Actions* property of the dispatcher in the **Object Inspector** and click on the ellipsis. When an action is selected in the action editor, its properties can be modified in the **Object Inspector**.

The action item includes properties that specify

- The target URL (see page 2281)
- The request method type (see page 2280)

Other properties that influence when the dispatcher fires an action item are described in

- Enabling and disabling action items (see page 2279)
- Choosing a default action item (see page 2278)

See Also

Adding Actions to the Dispatcher (see page 2277)

Responding to Request Messages with Action Items (see page 2280)

The Web Dispatcher (see page 2287)

3.2.5.3.3.3.4 Enabling and Disabling Action Items

Each action item has an Enabled property that can be used to enable or disable that action item. By setting *Enabled* to *False*, you disable the action item so that it is not considered by the dispatcher when it looks for an action item to handle a request.

A BeforeDispatch event handler can control which action items should process a request by changing the *Enabled* property of the action items before the dispatcher begins matching them to the request message.

Warning: Changing the *Enabled* property of an action during execution may cause unexpected results for subsequent requests. If the Web server application is a DLL that caches Web modules, the initial state will not be reinitialized for the next request. Use

the *BeforeDispatch* event to ensure that all action items are correctly initialized to their appropriate starting states.

The Target URL (see page 2281)

The Request Method Type (see page 2280)

Choosing a Default Action Item (see page 2278)

Dispatching Request Messages (see page 2281)

3.2.5.3.3.3.5 Responding to Request Messages with Action Items

The real work of the Web server application is performed by action items when they execute. When the Web dispatcher fires an action item, that action item can respond to the current request message in two ways:

- If the action item has an associated producer component as the value of its Producer property, that producer automatically assigns the Content of the response message using its Content method. The Internet page of the **Tool palette** includes a number of content producer components that can help construct an HTML page for the content of the response message.
- After the producer has assigned any response content (if there is an associated producer), the action item receives an OnAction event. The OnAction event handler is passed the TWebRequest object that represents the HTTP request message and a TWebResponse object to fill with any response information.

If the action item's content can be generated by a single content producer, it is simplest to assign the content producer as the action item's *Producer* property. However, you can always access any content producer from the *OnAction* event handler as well. The *OnAction* event handler allows more flexibility, so that you can use multiple content producers, assign response message properties, and so on.

Both the content-producer component and the *OnAction* event handler can use any objects or runtime library methods to respond to request messages. They can access databases, perform calculations, construct or select HTML documents, and so on. For more information about generating response content using content-producer components, see Generating the content of response messages (see page 2269).

Sending the response

An *OnAction* event handler can send the response back to the Web client by using the methods of the *TWebResponse* object. However, if no action item sends the response to the client, it will still get sent by the Web server application as long as the last action item to look at the request indicates that the request was handled.

Using multiple action items

You can respond to a request from a single action item, or divide the work up among several action items. If the action item does not completely finish setting up the response message, it must signal this state in the *OnAction* event handler by setting the *Handled* parameter to *False*.

If many action items divide up the work of responding to request messages, each setting *Handled to False* so that others can continue, make sure the default action item leaves the Handled parameter set to *True*. Otherwise, no response will be sent to the Web client.

When dividing the work among several action items, either the *OnAction* event handler of the default action item or the *AfterDispatch* event handler of the dispatcher should check whether all the work was done and set an appropriate error code if it is not.

See Also

Adding Actions to the Dispatcher (see page 2277)

The Web Dispatcher (see page 2287)

3.2.5.3.3.3.6 The Request Method Type

The MethodType property of an action item indicates what type of request messages it can process. The dispatcher compares

the *MethodType* property of an action item to the *MethodType* of the request message. *MethodType* can take one of the following values:

MethodType values

Value	Meaning
mtGet	The request is asking for the information associated with the target URI to be returned in a response message.
mtHead	The request is asking for the header properties of a response, as if servicing an mtGet request, but omitting the content of the response.
mtPost	The request is providing information to be posted to the Web application.
mtPut	The request asks that the resource associated with the target URI be replaced by the content of the request message.
mtAny	Matches any request method type, including mtGet, mtHead, mtPut, and mtPost.

The Target URL (see page 2281)

Enabling and Disabling Action Items (see page 2279)

Choosing a Default Action Item (see page 2278)

HTTP Request Header Information (see page 2252)

3.2.5.3.3.3.7 The Target URL

The dispatcher compares the PathInfo property of an action item to the *PathInfo* of the request message. The value of this property should be the path information portion of the URL for all requests that the action item is prepared to handle. For example, given this URL,

```
http://www.TSite.com/art/gallery.dll/mammals?animal=dog&color=black
```

and assuming that the `/gallery.dll` part indicates the Web server application, the path information portion is

```
/mammals
```

Use path information to indicate where your Web application should look for information when servicing requests, or to divide you Web application into logical subservices.

Choosing a Default Action Item (see page 2278)

Parts of a Uniform Resource Locator (see page 2253)

3.2.5.3.3.4 Dispatching Request Messages

When the dispatcher receives the client request, it generates a BeforeDispatch event. This provides your application with a chance to preprocess the request message before it is seen by any of the action items (see page 2278).

Next, the dispatcher iterates over its list of action items, looking for an entry that matches the PathInfo portion of the request message's target URL and that also provides the service specified as the method of the request message. It does this by comparing the PathInfo and MethodType properties of the *TWebRequest* object with the property of the same name on the action item.

When the dispatcher finds an appropriate action item, it causes that action item to fire. When the action item fires, it does one of

the following:

- Fills in the response content and sends the response or signals that the request is completely handled.
- Adds to the response and then allows other action items to complete the job.
- Defers the request to other action items.

After checking all its action items, if the message is not handled the dispatcher checks any specially registered auto-dispatching components that do not use action items. These components are specific to multi-tiered database applications, which are described in Building Web applications using InternetExpress (see page 1522)

If, after checking all the action items and any specially registered auto-dispatching components, the request message has still not been fully handled, the dispatcher calls the default action item. The default action item does not need to match either the target URL or the method of the request.

If the dispatcher reaches the end of the action list (including the default action, if any) and no actions have been triggered, nothing is passed back to the server. The server simply drops the connection to the client.

If the request is handled by the action items, the dispatcher generates an AfterDispatch event. This provides a final opportunity for your application to check the response that was generated, and make any last minute changes.

Adding Actions to the Dispatcher (see page 2277)

3.2.5.3.3.5 Creating HTTP response messages

Topics

Name	Description
Creating HTTP Response Messages (see page 2283)	When the Web server application creates a TWebRequest descended object for an incoming HTTP request message, it also creates a corresponding object descended from *TWebResponse* to represent the response message that will be sent in return. For example, in NSAPI and ISAPI applications, the response message is encapsulated by a TISAPIResponse object, and Console CGI applications use TCGIResponse objects. The action items that generate the response to a Web client request fill in the properties of the response object. In some cases, this may be as simple as returning an error code or redirecting the request to another URI. In... more (see page 2283)
Describing the Content (see page 2284)	Several properties describe the content of the response. ContentType gives the media type of the response, and ContentVersion is the version number for that media type. ContentLength gives the length of the response. If the content is encoded (such as for data compression), indicate this with the ContentEncoding property. If the content came from another URI, this should be indicated in the DerivedFrom property. If the value of the content is time-sensitive, the LastModified property and the Expires property indicate whether the value is still valid. The Title property can provide descriptive information about the content.
Describing the Server Application (see page 2284)	Some of the response header properties describe the capabilities of the Web server application. The Allow property indicates the methods to which the application can respond. The Server property gives the name and version number of the application used to generate the response. The Cookies property can hold state information about the client's use of the server application which is included in subsequent request messages.
Filling in the Response Header (see page 2284)	Most of the properties of the TWebResponse object represent the header information of the HTTP response message that is sent back to the Web client. An action item sets these properties from its *OnAction* event handler. Not every response message needs to specify a value for every one of the header properties. The properties that should be set depend on the nature of the request and the status of the response. Use the response object properties for • Indicating the response status (see page 2285) • Indicating the need for client action (see page 2284) • Describing the server application (see page 2284) • Describing the content (see page 2284)

Indicating the Need for Client Action (see page 2284)	When the status code is in the 300-399 range, the client must perform further action before the Web server application can complete its request. If you need to redirect the client to another URI, or indicate that a new URI was created to handle the request, set the Location property. If the client must provide a password before you can proceed, set the WWWAuthenticate property.
Indicating the Response Status (see page 2285)	Every response message must include a status code that indicates the status of the response. You can specify the status code by setting the StatusCode property. The HTTP standard defines a number of standard status codes with predefined meanings. In addition, you can define your own status codes using any of the unused possible values. Each status code is a three-digit number where the most significant digit indicates the class of the response, as follows: • 1xx: Informational (The request was received but has not been fully processed). • 2xx: Success (The request was received, understood, and accepted). • 3xx: Redirection (Further action... more (see page 2285)
Sending the Response (see page 2285)	If you are sure there is no more work to be done in response to a request message, you can send a response directly from an OnAction event handler. The response object provides two methods for sending a response: SendResponse and SendRedirect. Call *SendResponse* to send the response using the specified content and all the header properties of the *TWebResponse* object. If you only need to redirect the Web client to another URI, the *SendRedirect* method is more efficient. If none of the event handlers send the response, the Web application object sends it after the dispatcher finishes. However, if... more (see page 2285)
Setting the Response Content (see page 2285)	For some requests, the response to the request message is entirely contained in the header properties of the response. In most cases, however, action item assigns some content to the response message. This content may be static information stored in a file, or information that was dynamically produced by the action item or its content producer. You can set the content of the response message by using either the Content property or the ContentStream property. The *Content* property is a string. Delphi strings are not limited to text values, so the value of the *Content* property can be a string... more (see page 2285)

3.2.5.3.3.5.1 Creating HTTP Response Messages

When the Web server application creates a TWebRequest descended object for an incoming HTTP request message, it also creates a corresponding object descended from *TWebResponse* to represent the response message that will be sent in return. For example, in NSAPI and ISAPI applications, the response message is encapsulated by a TISAPIResponse object, and Console CGI applications use TCGIResponse objects.

The action items that generate the response to a Web client request fill in the properties of the response object. In some cases, this may be as simple as returning an error code or redirecting the request to another URI. In other cases, this may involve complicated calculations that require the action item to fetch information from other sources and assemble it into a finished form. Most request messages require some response, even if it is only the acknowledgment that a requested action was carried out.

Responding to HTTP requests involves

- Filling in the response header (see page 2284)
- Setting the response content (see page 2285)
- Sending the response (see page 2285)

See Also

Action Items (see page 2278)

Setting the Response Content (see page 2285)

Generating the Content of Response Messages (see page 2269)

3.2.5.3.3.5.3 Describing the Server Application

Some of the response header properties describe the capabilities of the Web server application. The Allow property indicates the methods to which the application can respond. The Server property gives the name and version number of the application used to generate the response. The Cookies property can hold state information about the client's use of the server application which is included in subsequent request messages.

See Also

Indicating the Response Status (see page 2285)

Indicating the Need for Client Action (see page 2284)

Describing the Content (see page 2284)

3.2.5.3.3.5.4 Filling in the Response Header

Most of the properties of the TWebResponse object represent the header information of the HTTP response message that is sent back to the Web client. An action item sets these properties from its *OnAction* event handler.

Not every response message needs to specify a value for every one of the header properties. The properties that should be set depend on the nature of the request and the status of the response.

Use the response object properties for

- Indicating the response status (see page 2285)
- Indicating the need for client action (see page 2284)
- Describing the server application (see page 2284)
- Describing the content (see page 2284)

See Also

Setting the Response Content (see page 2285)

Sending the Response (see page 2285)

3.2.5.3.3.5.5 Indicating the Need for Client Action

When the status code is in the 300-399 range, the client must perform further action before the Web server application can complete its request. If you need to redirect the client to another URI, or indicate that a new URI was created to handle the

request, set the Location property. If the client must provide a password before you can proceed, set the WWWAuthenticate property.

See Also

Indicating the Response Status (see page 2285)

Describing the Server Application (see page 2284)

Describing the Content (see page 2284)

3.2.5.3.3.5.6 Indicating the Response Status

Every response message must include a status code that indicates the status of the response. You can specify the status code by setting the StatusCode property. The HTTP standard defines a number of standard status codes with predefined meanings. In addition, you can define your own status codes using any of the unused possible values.

Each status code is a three-digit number where the most significant digit indicates the class of the response, as follows:

- 1xx: Informational (The request was received but has not been fully processed).
- 2xx: Success (The request was received, understood, and accepted).
- 3xx: Redirection (Further action by the client is needed to complete the request).
- 4xx: Client Error (The request cannot be understood or cannot be serviced).
- 5xx: Server Error (The request was valid but the server could not handle it).

Associated with each status code is a string that explains the meaning of the status code. This is given by the ReasonString property. For predefined status codes, you do not need to set the *ReasonString* property. If you define your own status codes, you should also set the *ReasonString* property.

See Also

Indicating the Need for Client Action (see page 2284)

Describing the Server Application (see page 2284)

Describing the Content (see page 2284)

3.2.5.3.3.5.7 Sending the Response

If you are sure there is no more work to be done in response to a request message, you can send a response directly from an OnAction event handler. The response object provides two methods for sending a response: SendResponse and SendRedirect. Call *SendResponse* to send the response using the specified content and all the header properties of the *TWebResponse* object. If you only need to redirect the Web client to another URI, the *SendRedirect* method is more efficient.

If none of the event handlers send the response, the Web application object sends it after the dispatcher finishes. However, if none of the action items indicate that they have handled the response, the application will close the connection to the Web client without sending any response.

See Also

Filling in the Response Header (see page 2284)

Setting the Response Content (see page 2285)

3.2.5.3.3.5.8 Setting the Response Content

For some requests, the response to the request message is entirely contained in the header properties of the response. In most cases, however, action item assigns some content to the response message. This content may be static information stored in a file, or information that was dynamically produced by the action item or its content producer.

You can set the content of the response message by using either the Content property or the ContentStream property.

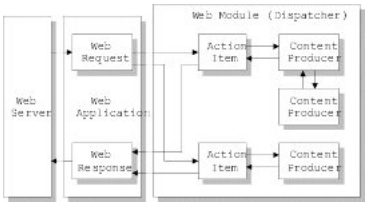
The *Content* property is a string. Delphi strings are not limited to text values, so the value of the *Content* property can be a string of HTML commands, graphics content such as a bit-stream, or any other MIME content type.

Use the *ContentStream* property if the content for the response message can be read from a stream. For example, if the response message should send the contents of a file, use a TFileStream object for the *ContentStream* property. As with the *Content* property, *ContentStream* can provide a string of HTML commands or other MIME content type. If you use the *ContentStream* property, do not free the stream yourself. The Web response object automatically frees it for you.

Note: If the value of the *ContentStream* property is not **nil**, the *Content* property is ignored.

See Also

Filling in the Response Header (see page 2284)



Sending the Response (see page 2285)

Generating the Content of Response Messages (see page 2269)

3.2.5.3.3.6 The Structure of a Web Broker Application

When the Web application (see page 2288) receives an HTTP request message, it creates a TWebRequest object to represent the HTTP request message, and a TWebResponse object to represent the response that should be returned. The application then passes these objects to the Web dispatcher (either the Web module or a *TWebDispatcher* component).

The Web dispatcher (see page 2287) controls the flow of the Web server application. The dispatcher maintains a collection of action items (*TWebActionItem*) that know how to handle certain types of HTTP request messages. The dispatcher identifies the appropriate action items or auto-dispatching components to handle the HTTP request message, and passes the request and response objects to the identified handler so that it can perform any requested actions or formulate a response message.

The action items are responsible for reading the request (see page 2274) and assembling a response message (see page 2283). Specialized content producer components aid the action items in dynamically generating the content of response messages (see page 2269), which can include custom HTML code or other MIME content. The content producers can make use of other content producers or descendants of *THTMLTagAttributes*, to help them create the content of the response message.

If you are creating the Web Client in a multi-tiered database application (see page 1522), your Web server application may include additional, auto-dispatching components that represent database information encoded in XML and database manipulation classes encoded in javascript. If you are creating a server that implements a Web Service (see page 2299), your Web server application may include an auto-dispatching component that passes SOAP-based messages on to an invoker that interprets and executes them. The dispatcher calls on these auto-dispatching components to handle the request message after it has tried all of its action items.

When all action items (or auto-dispatching components) have finished creating the response by filling out the *TWebResponse* object, the dispatcher passes the result back to the Web application. The application sends the response on to the client via the Web server.

Types of Web Server Applications (see page 2249)

Creating Web Server Applications with Web Broker (see page 2287)

3.2.5.3.3.7 The Web dispatcher

Topics

Name	Description
The Web Dispatcher (see page 2287)	If you are using a Web module (see page 2288), it acts as a Web dispatcher. If you are using a pre-existing data module, you must add a single dispatcher component (TWebDispatcher) to that data module. The dispatcher maintains a collection of action items that know how to handle certain kinds of request messages. When the Web application passes a request object and a response object to the dispatcher, it is responsible for dispatching the request message (see page 2281). Set up the Web dispatcher by adding actions to the dispatcher (see page 2277).

3.2.5.3.3.7.1 The Web Dispatcher

If you are using a Web module (see page 2288), it acts as a Web dispatcher. If you are using a pre-existing data module, you must add a single dispatcher component (TWebDispatcher) to that data module. The dispatcher maintains a collection of action items that know how to handle certain kinds of request messages. When the Web application passes a request object and a response object to the dispatcher, it is responsible for dispatching the request message (see page 2281).

Set up the Web dispatcher by adding actions to the dispatcher (see page 2277).

See Also

Action Items (see page 2278)

Accessing Client Request Information (see page 2274)

Creating HTTP Response Messages (see page 2283)

Generating the Content of Response Messages (see page 2269)

3.2.5.3.4 Creating Web Server Applications with Web Broker

Web Broker components (located on the Internet tab of the **Tool palette**) enable you to create event handlers that are associated with a specific Uniform Resource Identifier (URI). When processing is complete, you can programmatically construct HTML or XML documents and transfer them to the client. You can use Web Broker components for cross-platform application development.

To create a new Web server application using the Web Broker architecture:

1. Select **File** ▶ **New** ▶ **Other**.
2. In the New Items dialog box, select the New tab under Delphi Projects and choose Web Server Application.
3. A dialog box appears, where you can select one of the Web server application types:

- ISAPI and NSAPI: Selecting this type of application sets up your project as a DLL, with the exported methods expected by the Web server. It adds the library header to the project file and the required entries to the uses list and exports clause of the project file.
- CGI stand-alone: Selecting this type of application sets up your project as a console application, and adds the required entries to the uses clause of the project file.
- Web Application Debugger stand-alone executable: Selecting this type of application sets up an environment for developing and testing Web server applications. This type of application is not intended for deployment. Choose the type of Web Server Application that communicates with the type of Web Server your application will use. This creates a new project configured to use Internet components.

Topics

Name	Description
The Web Application Object (see page 2288)	The project that is set up for your Web application contains a global variable named *Application*. *Application* is a descendant of *TWebApplication* that is appropriate to the type of application you are creating. It runs in response to HTTP request messages received by the Web server. **Warning:** Do not include the Forms or QForms unit in the project **uses** clause after the CGIApp, ApacheApp, ApacheTwoApp, or ISAPIApp unit. Forms also declares a global variable named *Application*, and if it appears after the CGIApp, ApacheApp, ApacheTwoApp, or ISAPIApp unit, *Application* will... more (see page 2288)
The Web Module (see page 2288)	The Web module (TWebModule) is a descendant of TDataModule and may be used in the same way: to provide centralized control for business rules and non-visual components in the Web application. Add any content producers that your application uses to generate response messages. These can be the built-in content producers such as TPageProducer, TDataSetPageProducer, TDataSetTableProducer, TQueryTableProducer and TInetXPageProducer or descendants of TCustomContentProducer that you have written yourself. If your application generates response messages that include material drawn from databases, you can add data access components or special components for writing a Web server that acts as a client in a (see page 1522)... more (see page 2288)

3.2.5.3.4.1 The Web Application Object

The project that is set up for your Web application contains a global variable named *Application*. *Application* is a descendant of *TWebApplication* that is appropriate to the type of application you are creating. It runs in response to HTTP request messages received by the Web server.

Warning: Do not include the Forms or QForms unit in the project **uses** clause after the CGIApp, ApacheApp, ApacheTwoApp, or ISAPIApp unit. Forms also declares a global variable named *Application*, and if it appears after the CGIApp, ApacheApp, ApacheTwoApp, or ISAPIApp unit, *Application* will be initialized to an object of the wrong type.

See Also

The Web Module (see page 2288)

3.2.5.3.4.2 The Web Module

The Web module (TWebModule) is a descendant of TDataModule and may be used in the same way: to provide centralized control for business rules and non-visual components in the Web application.

Add any content producers that your application uses to generate response messages. These can be the built-in content producers such as TPageProducer, TDataSetPageProducer, TDataSetTableProducer, TQueryTableProducer and TInetXPageProducer or descendants of TCustomContentProducer that you have written yourself. If your application generates response messages that include material drawn from databases, you can add data access components or special components for writing a Web server that acts as a client in a multi-tiered database application (see page 1522).

In addition to storing non-visual components and business rules, the Web module also acts as a Web dispatcher (see page 2287), matching incoming HTTP request messages to action items that generate the responses to those requests.

You may have a data module already that is set up with many of the non-visual components and business rules that you want to use in your Web application. You can replace the Web module with your pre-existing data module. Simply delete the automatically generated Web module and replace it with your data module. Then, add a TWebDispatcher component to your data module, so that it can dispatch request messages to action items, the way a Web module can. If you want to change the way action items are chosen to respond to incoming HTTP request messages, derive a new dispatcher component from TCustomWebDispatcher, and add that to the data module instead.

Your project can contain only one dispatcher. This can either be the Web module that is automatically generated when you create the project, or the TWebDispatcher component that you add to a data module that replaces the Web module. If a second

data module containing a dispatcher is created during execution, the Web server application generates a runtime error.

Note: The Web module that you set up at design time is actually a template. In ISAPI and NSAPI applications, each request message spawns a separate thread, and separate instances of the Web module and its contents are created dynamically for each thread.

Warning: The Web module in a DLL-based Web server application is cached for later reuse to increase response time. The state of the dispatcher and its action list is not reinitialized between requests. Enabling or disabling action items during execution may cause unexpected results when that module is used for subsequent client requests.

Using Data Modules and Remote Data Modules (see page 1912)

3.2.5.4 Using Web Services

Topics

Name	Description
Using Web Services (see page 2291)	Web Services are self-contained modular applications that can be published and invoked over the Internet. Web Services provide well-defined interfaces that describe the services provided. Unlike Web server applications that generate Web pages for client browsers, Web Services are not designed for direct human interaction. Rather, they are accessed programmatically by client applications. Web Services are designed to allow a loose coupling between client and server. That is, server implementations do not require clients to use a specific platform or programming language. In addition to defining interfaces in a language-neutral fashion, they are designed to allow multiple communications mechanisms as... more (see page 2291)
Understanding Invokable Interfaces (see page 2292)	Servers that support Web Services are built using invokable interfaces. Invokable interfaces are interfaces that are compiled to include runtime type information (RTTI). On the server, this RTTI is used when interpreting incoming method calls from clients so that they can be correctly marshaled. On clients, this RTTI is used to dynamically generate a method table for making calls to the methods of the interface. To create an invokable interface, you need only compile an interface with the {$M+} compiler option. The descendant of any invokable interface is also invokable. However, if an invokable interface descends from another interface that... more (see page 2292)
Using Nonscalar Types in Invokable Interfaces (see page 2293)	The Web Services architecture supports the following scalar types for both Delphi and C++:
Registering Nonscalar Types (see page 2294)	Before an invokable interface can use any types other than the built-in scalar types listed in Using nonscalar types in invokable interfaces (see page 2293), the application must register the type with the remotable type registry. To access the remotable type registry, you must add the InvokeRegistry unit to your uses clause. This unit declares a global function, *RemTypeRegistry*, which returns a reference to the remotable type registry. **Note:** On clients, the code to register types with the remotable type registry is generated automatically when you import a WSDL document. For servers, remotable types are registered for you automatically when... more (see page 2294)
Using Remotable Objects (see page 2296)	Use TRemotable as a base class when defining a class to represent a complex data type on an invokable interface. For example, in the case where you would ordinarily pass a record or struct as a parameter, you would instead define a *TRemotable* descendant where every member of the record or struct is a published property on your new class.

Remotable Object Example (see page 2297)	This example shows how to create a remotable object for a parameter on an invokable interface where you would otherwise use an existing class. In this example, the existing class is a string list (*TStringList*). To keep the example small, it does not reproduce the *Objects* property of the string list. Because the new class is not scalar, it descends from *TRemotable* rather than *TRemotableXS*. It includes a published property for every property of the string list you want to communicate between the client and server. Each of these remotable properties corresponds to a remotable type. In... more (see page 2297)
Writing Servers that Support Web Services (see page 2299)	In addition to the invokable interfaces and the classes that implement them, your server requires two components: a dispatcher and an invoker. The dispatcher (THTTPSoapDispatcher) receives incoming SOAP messages and passes them on to the invoker. The invoker (THTTPSOAPPascalInvoker) interprets the SOAP message, identifies the invokable interface it calls, executes the call, and assembles the response message. **Note:** *THTTPSoapDispatcher* and*THTTPSoapPascalInvoker are designed to respond to HTTP messages containing a SOAP request. The underlying architecture is sufficiently general, however, that it can support other protocols with the substitution of different dispatcher and invoker components.* *Once you register your invokable interfaces... more (see page 2299)*
Using the SOAP Application Wizard (see page 2300)	Web Service applications are a special form of Web Server application. Because of this, support for Web Services is built on top of the Web Broker architecture. To understand the code that the SOAP Application wizard generates, therefore, it is helpful to understand the Web Broker architecture. Information about Web Server applications in general, and Web Broker in particular, can be found in Creating Internet server applications (see page 2251) and Using Web Broker (see page 2272). To launch the SOAP application wizard, choose **File** ▶ **New** ▶ **Other**, and on the WebServices page, double-click the Soap Server Application icon. Choose the type of Web server... more (see page 2300)
Adding New Web Services (see page 2301)	To add a new Web Service interface to your server application, choose **File** ▶ **New** ▶ **Other**, and on the WebServices page double-click on the icon labeled SOAP Server Interface. The Add New Web Service wizard lets you specify the name of the invokable interface you want to expose to clients, and generates the code to declare and register the interface and its implementation class. By default, the wizard also generates comments that show sample methods and additional type definitions, to help you get started in editing the generated files.
Using the WSDL Importer (see page 2302)	To use the WSDL importer, choose File|New|Other, and on the WebServices page double-click the icon labeled WSDL importer. In the dialog that appears, specify the file name of a WSDL document (or XML file) or provide the URL where that document is published. **Note:** If you do not know the URL for the WSDL document you want to import, you can browse for one by clicking the button labeled Search UDDI. This launches the UDDI browser. **Tip:** An advantage of using the UDDI browser, even if you know the location of the WSDL document, is that when you locate... more (see page 2302)
Defining and Using SOAP Headers (see page 2303)	The SOAP encoding of a request to your Web Service application and of the response your application sends include a set of header nodes. Some of these, such as the SOAP Action header, are generated and interpreted automatically. However, you can also define your own headers to customize the communication between your server and its clients. Typically, these headers contain information that is associated with the entire invokable interface, or even with the entire application, rather than just the method that is the subject of a single message.
Creating Custom Exception Classes for Web Services (see page 2305)	When your Web Service application raises an exception in the course of trying to execute a SOAP request, it automatically encodes information about that exception in a SOAP fault packet, which it returns instead of the results of the method call. The client application then raises the exception. By default, the client application raises a generic exception of type ERemotableException with the information from the SOAP fault packet. You can transmit additional, application-specific information by deriving an ERemotableException descendant. The values of any published properties you add to the exception class are included in the SOAP fault packet so that... more (see page 2305)

Generating WSDL Documents for a Web Service Application (see page 2306)	To allow client applications to know what Web Services your application makes available, you can publish a WSDL document that describes your invokable interfaces and indicates how to call them. To publish a WSDL document that describes your Web Service, include a TWSDLHTMLPublish component in your Web Module. (The SOAP Server Application wizard adds this component by default.) *TWSDLHTMLPublish* is an auto-dispatching component, which means it automatically responds to incoming messages that request a list of WSDL documents for your Web Service. Use the WebDispatch property to specify the path information of the URL that clients must use to access... more (see page 2306)
Writing Clients for Web Services (see page 2307)	You can write clients that access Web Services that you have written, or any other Web Service that is defined in a WSDL document. There are three steps to writing an application that is the client of a Web Service: • Importing the definitions from a WSDL document (see page 2307). • Obtaining an invokable interface and calling it to invoke the Web Service (see page 2307). • Processing the headers of the SOAP messages that pass between the client and the server (see page 2310).
Importing WSDL Documents (see page 2307)	Before you can use a Web Service, your application must define and register the invokable interfaces and types that are included in the Web Service application. To obtain these definitions, you can import a WSDL document (see page 2302) (or XML file) that defines the service. The WSDL importer creates a unit that defines and registers the interfaces, headers, and types you need to use.
Calling Invokable Interfaces (see page 2307)	To call an invokable interface, your client application must include any definitions of the invokable interfaces and any remotable classes that implement complex types. If the server is written in Delphi or C++Builder, you can use the same units that the server application uses to define and register these interfaces and classes instead of the files generated by importing a WSDL file. Be sure that the unit uses the same namespace URI and SOAPAction header when it registers invokable interfaces. These values can be explicitly specified in the code that registers the interfaces, or it can be automatically generated. If... more (see page 2307)
Processing Headers in Client Applications (see page 2310)	If the Web Service application you are calling expects your client to include any headers in its requests or if its response messages include special headers, your client application needs the definitions of the header classes that correspond to these headers. When you import a WSDL document that describes the Web Service application, the importer automatically generates code to declare these header classes and register them with the remotable type registry. If the server is written in Delphi, you can use the same units that the server application uses to define and register these header classes instead of the files... more (see page 2310)

3.2.5.4.1 Using Web Services

Web Services are self-contained modular applications that can be published and invoked over the Internet. Web Services provide well-defined interfaces that describe the services provided. Unlike Web server applications that generate Web pages for client browsers, Web Services are not designed for direct human interaction. Rather, they are accessed programmatically by client applications.

Web Services are designed to allow a loose coupling between client and server. That is, server implementations do not require clients to use a specific platform or programming language. In addition to defining interfaces in a language-neutral fashion, they are designed to allow multiple communications mechanisms as well.

Support for Web Services is designed to work using SOAP (Simple Object Access Protocol). SOAP is a standard lightweight protocol for exchanging information in a decentralized, distributed environment. It uses XML to encode remote procedure calls and typically uses HTTP as a communications protocol. For more information about SOAP, see the SOAP specification available at

`http://www.w3.org/TR/SOAP/`

Note: Although the components that support Web Services are built to use SOAP and HTTP, the framework is sufficiently

general that it can be expanded to use other encoding and communications protocols.

In addition to letting you build SOAP-based Web Service applications (servers), special components and wizards let you build clients of Web Services that use either a SOAP encoding or a Document Literal style. The Document Literal style is used in .Net Web Services.

Web Service applications publish information on what interfaces are available and how to call them using a WSDL (Web Service Definition Language) document. On the server side, your application can publish a WSDL document that describes your Web Service. On the client side, a wizard or command-line utility can import a published WSDL document, providing you with the interface definitions and connection information you need. If you already have a WSDL document that describes the Web service you want to implement, you can generate the server-side code as well when importing the WSDL document.

The following topics describe support for working with Web Services in greater detail:

- Understanding invokable interfaces (see page 2292)
- Writing servers that support Web Services (see page 2299)
- Writing clients for Web Services (see page 2307)

Working with Sockets (see page 2337)

Using Web Services (chapter index) (see page 2289)

3.2.5.4.2 Understanding Invokable Interfaces

Servers that support Web Services are built using invokable interfaces. Invokable interfaces are interfaces that are compiled to include runtime type information (RTTI). On the server, this RTTI is used when interpreting incoming method calls from clients so that they can be correctly marshaled. On clients, this RTTI is used to dynamically generate a method table for making calls to the methods of the interface.

To create an invokable interface, you need only compile an interface with the {$M+} compiler option. The descendant of any invokable interface is also invokable. However, if an invokable interface descends from another interface that is not invokable, your Web Service can only use the methods defined in the invokable interface and its descendants. Methods inherited from the non-invokable ancestors are not compiled with type information and so can't be used as part of the Web Service.

When defining a Web service, you can derive an invokable interface from the base invokable interface, IInvokable. *IInvokable* is defined in the System unit. *IInvokable* is the same as the base interface (*IInterface*), except that it is compiled using the {$M+} compiler option. The {$M+} compiler option ensures that the interface and all its descendants include RTTI.

For example, the following code defines an invokable interface that contains two methods for encoding and decoding numeric values:

```
IEncodeDecode = interface(IInvokable)
['{C527B88F-3F8E-1134-80e0-01A04F57B270}']
    function EncodeValue(Value: Integer): Double; stdcall;
    function DecodeValue(Value: Double): Integer; stdcall;
end;
__interface INTERFACE_UUID("{C527B88F-3F8E-1134-80e0-01A04F57B270}") IEncodeDecode :
    public IInvokable
{
public:
  virtual double __stdcall EncodeValue(int Value) = 0 ;
  virtual int __stdcall DecodeValue(double Value) = 0 ;
};
```

Note: An invokable interface can use overloaded methods, but only if the different overloads can be distinguished by parameter count. That is, one overload must not have the same number of parameters as another, including the possible number of

parameters when default parameters are taken into account.

Before a Web Service application can use this invokable interface, it must be registered with the invocation registry. On the server, the invocation registry entry allows the invoker component (THTTPSOAPPascalInvoker) to identify an implementation class to use for executing interface calls. On client applications, an invocation registry entry allows remote interfaced objects (THTTPRio) to look up information that identifies the invokable interface and supplies information on how to call it.

Typically, your Web Service client or server creates the code to define invokable interfaces either by importing a WSDL document or using the Web Service wizard. By default, when the WSDL importer or Web Service wizard generates an interface, the definition is added to a unit with the same name as the Web Service. This unit includes both the interface definition and code to register the interface with the invocation registry. The invocation registry is a catalog of all registered invokable interfaces, their implementation classes, and any functions that create instances of the implementation classes. It is accessed using the global *InvRegistry* function, which is defined in the InvokeRegistry unit.

The definition of the invokable interface is added to the interface section of the unit, and the code to register the interface goes in the initialization section. The registration code looks like the following:

```
initialization
  InvRegistry.RegisterInterface(TypeInfo(IEncodeDecode));
end.
static void RegTypes()
{
  InvRegistry()->RegisterInterface(__delphirtti(IEncodeDecode), "", "");
}
#pragma startup RegTypes 32
```

Note: The implementation section's uses clause must include the InvokeRegistry unit so that the call to the *InvRegistry* function is defined.

The interfaces of Web Services must have a namespace to identify them among all the interfaces in all possible Web Services. The previous example does not supply a namespace for the interface. When you do not explicitly supply a namespace, the invocation registry automatically generates one for you. This namespace is built from a string that uniquely identifies the application (the *AppNamespacePrefix* variable), the interface name, and the name of the unit in which it is defined. If you do not want to use the automatically-generated namespace, you can specify one explicitly using a second parameter to the *RegisterInterface* call.

You can use the same unit file to define an invokable interface for both client and server applications. If you are doing this, it is a good idea to keep the unit that defines your invokable interfaces separate from the unit in which you write the classes that implement them. Because the generated namespace includes the name of the unit in which the interface is defined, sharing the same unit in both client and server applications enables them to automatically use the same namespace, as long as they both use the same value for the *AppNamespacePrefix* variable.

The preceding example uses only scalar types (integers and doubles) in the methods of the interface. You can use nonscalar types as well, but they require a bit more work.

See Also

Using Nonscalar Types in Invokable Interfaces (see page 2299)

3.2.5.4.3 Using Nonscalar Types in Invokable Interfaces

The Web Services architecture supports the following scalar types for both Delphi and C++:

Boolean	ByteBool	WordBool
LongBool	Char	Byte
ShortInt	SmallInt	Word
Integer	Cardinal	LongInt

Int64	Single	Double
Extended	string	WideString
Currency	TDateTime	Variant

The following additional scalar types are supported for C++:

bool	unsigned short	_int64
char	int	AnsiString
signed char	unsigned	float
unsigned char	long	double
short	unsigned long	long double

You need not do anything special when you use these scalar types on an invokable interface. If your interface includes any properties or methods that use other types, however, your application must register those types with the remotable type registry (see page 2294).

Dynamic arrays can be used in invokable interfaces. They must be registered with the remotable type registry, but this registration happens automatically when you register the interface. The remotable type registry extracts all the information it needs from the type information that the compiler generates.

Note: You should avoid defining multiple dynamic array types with the same element type. Because the compiler treats these as transparent types that can be implicitly cast one to another, it doesn't distinguish their runtime type information. As a result, the remotable type registry can't distinguish the types. This is not a problem for servers, but can result in clients using the wrong type definition. As an alternate approach, you can use remotable clases to represent array types.

Note: The dynamic array types defined in the Types unit are automatically registered for you, so your application does not need to add any special registration code for them. One of these in particular, *TByteDynArray*, deserves special notice because it maps to a 'base64' block of binary data, rather than mapping each array element separately the way the other dynamic array types do.

Enumerated types and types that map directly to one of the automatically-marshaled scalar types can also be used in an invokable interface. As with dynamic array types, they are automatically registered with the remotable type registry.

For any other types, such as static arrays, structs or records, sets, interfaces, or classes, you must map the type to a remotable class (see page 2296). A remotable class is a class that includes runtime type information (RTTI). Your interface must then use the remotable class instead of the corresponding static array, struct or record, set, interface, or class. Any remotable classes you create must be registered with the remotable type registry. As with other types, this registration happens automatically.

See Also

Understanding Invokable Interfaces (see page 2292)

Using Nonscalar Types in Invokable Interfaces (see page 2299)

3.2.5.4.4 Registering Nonscalar Types

Before an invokable interface can use any types other than the built-in scalar types listed in Using nonscalar types in invokable interfaces (see page 2293), the application must register the type with the remotable type registry. To access the remotable type registry, you must add the InvokeRegistry unit to your uses clause. This unit declares a global function, *RemTypeRegistry*, which returns a reference to the remotable type registry.

Note: On clients, the code to register types with the remotable type registry is generated automatically when you import a WSDL document. For servers, remotable types are registered for you automatically when you register an interface that uses

them. You only need to explicitly add code to register types if you want to specify the namespace or type name rather than using the automatically-generated values.

The remotable type registry has two methods that you can use to register types: RegisterXSInfo and RegisterXSClass. The first (*RegisterXSInfo*) lets you register a dynamic array or other type definition. The second (*RegisterXSClass*) is for registering remotable classes that you define to represent other types.

If you are using dynamic arrays or enumerated types, the invocation registry can get the information it needs from the compiler-generated type information. Thus, for example, your interface may use a type such as the following:

```
type
  TDateTimeArray = array of TXSDateTime;
typedef DynamicArray<TXSDateTime> TDateTimeArray;
```

This type is registered automatically when you register the invokable interface. However, if you want to specify the namespace in which the type is defined or the name of the type, you must add code to explicitly register the type using the *RegisterXSInfo* method of the remotable type registry.

The registration goes in the initialization section of the unit where you declare or use the dynamic array:

```
RemTypeRegistry.RegisterXSInfo(TypeInfo(TDateTimeArray), MyNameSpace, 'DTarray', 'DTarray');
void RegTypes()
{
  RemTypeRegistry()->RegisterXSInfo(__arraytypeinfo(TDateTimeArray),
        MyNameSpace, "DTarray", "DTarray");
  InvRegistry()->RegisterInterface(__delphirtti(ITimeServices));
}
```

The first parameter of *RegisterXSInfo* is the type information for the type you are registering. The second parameter is the namespace URI for the namespace in which the type is defined. If you omit this parameter or supply an empty string, the registry generates a namespace for you. The third parameter is the name of the type as it appears in native code. If you omit this parameter or supply an empty string, the registry uses the type name from the type information you supplied as the first parameter. The final parameter is the name of the type as it appears in WSDL documents. If you omit this parameter or supply an empty string, the registry uses the native type name (the third parameter).

Registering a remotable class (see page 2296) is similar, except that you supply a class reference rather than a type information pointer. For example, the following line comes from the XSBuiltIns unit. It registers *TXSDateTime*, a *TRemotable* descendant that represents *TDateTime* values:

```
RemClassRegistry.RegisterXSClass(TXSDateTime, XMLSchemaNameSpace, 'dateTime', '',True);
void RegTypes()
{
  RemTypeRegistry()->RegisterXSclass(__classid(TXSDateTime), XMLSchemaNameSpace, "dateTime",
"", true);
  InvRegistry()->RegisterInterface(__delphirtti(ITimeServices));
}
```

The first parameter is class reference for the remotable class that represents the type. The second is a uniform resource identifier (URI) that uniquely identifies the namespace of the new class. If you supply an empty string, the registry generates a URI for you. The third and fourth parameters specify the native and external names of the data type your class represents. If you omit the fourth parameter, the type registry uses the third parameter for both values. If you supply an empty string for both parameters, the registry uses the class name. The fifth parameter indicates whether the value of class instances can be transmitted as a string. You can optionally add a sixth parameter (not shown here) to control how multiple references to the same object instance should be represented in SOAP packets.

See Also

Using Remotable Objects (see page 2296)

3.2.5.4.5 Using Remotable Objects

Use TRemotable as a base class when defining a class to represent a complex data type on an invokable interface. For example, in the case where you would ordinarily pass a record or struct as a parameter, you would instead define a *TRemotable* descendant where every member of the record or struct is a published property on your new class.

The following has been deprecated:
You can control whether the published properties of your TRemotable descendant appear as element nodes or attributes in the corresponding SOAP encoding of the type. To make the property an attribute, use the stored directive on the property definition, assigning a value of *AS_ATTRIBUTE*: property MyAttribute: Boolean read FMyAttribute write FMyAttribute stored AS_ATTRIBUTE; __property bool MyAttribute = {read=FMyAttribute, write=FMyAttribute, stored= AS_ATTRIBUTE; If you do not include a stored directive, or if you assign any other value to the stored directive (even a function that returns *AS_ATTRIBUTE*), the property is encoded as a node rather than an attribute.

The *AS_ATTRIBUTE* feature has been deprecated. It still works for legacy code, but the preferred approach is to use the index value of a property. The index property allows you to specify whether a property is an attribute, an unbounded element, an optional element, a text value, or can have a value of NULL. The support for optional elements relies on the stored property attribute, which points to a method that returns *TRUE* if the property has been specified, *FALSE* if not.

The following example illustrates the support for an optional attribute and a text element:

```
class Thumbnail : public TRemotable {
private:
   WideString      FText;
   WideString      FExists;
   bool            FExists_Specified;
   void __fastcall SetExists(int Index, WideString _prop_val)
   {  FExists = _prop_val; FExists_Specified = true;  }
   bool __fastcall Exists_Specified(int Index)
   {  return FExists_Specified;  }
  __published:
   __property WideString       Text = { index=(IS_TEXT), read=FText, write=FText };
   __property WideString     Exists = { index=(IS_ATTR|IS_OPTN), read=FExists,
write=SetExists, stored = Exists_Specified };
};
```

If the value of your new *TRemotable* descendant represents a scalar type in a WSDL document, you should use TRemotableXS as a base class instead. *TRemotableXS* is a *TRemotable* descendant that introduces two methods for converting between your new class and its string representation. Implement these methods by overriding the XSToNative and NativeToXS methods.

For certain commonly-used XML scalar types, the XSBuiltIns unit already defines and registers remotable classes for you. These are listed in the following table:

Remotable classes

XML type	remotable class
dateTime timeInstant	TXSDateTime
date	TXSDate
time	TXSTime
durationtimeDuration	TXSDuration
decimal	TXSDecimal
hexBinary	TXSHexBinary
string	TXSString
boolean	TXSBoolean

integer	TXSInteger
long	TXSLong

Note: You can use *TXSString*, *TXSBoolean*, *TXSInteger* and *TXSLong* for cases where a string, boolean, integer, or long value can be nil (NULL or 0 for C++). You can use the type *TXMLData* when the data sent or received is unspecified. *TXMLData* can be used for passing raw XML—such as a schema—in a SOAP message.

After you define a remotable class, it must be registered with the remotable type registry, as described in Registering nonscalar types (see page 2294). This registration happens automatically on servers when you register the interface that uses the class. On clients, the code to register the class is generated automatically when you import the WSDL document that defines the type. For an example of defining and registering a remotable class, see Remotable object example (see page 2297).

Tip: It is a good idea to implement and register *TRemotable* descendants in a separate unit from the rest of your server application, including from the units that declare and register invokable interfaces. In this way, you can use the type for more than one interface.

Representing attachments

One important *TRemotable* descendant is TSoapAttachment. This class represents an attachment. It can be used as the value of a parameter or the return value of a method on an invokable interface. Attachments are sent with SOAP messages as separate parts in a multipart form.

When a Web Service application or the client of a Web Service receives an attachment, it writes the attachment to a temporary file. *TSoapAttachment* lets you access that temporary file or save its content to a permanent file or stream. When the application needs to send an attachment, it creates an instance of *TSoapAttachment* and assigns its content by specifying the name of a file, supplying a stream from which to read the attachment, or providing a string that represents the content of the attachment.

Managing the lifetime of remotable objects

One issue that arises when using *TRemotable* descendants is the question of when they are created and destroyed. Obviously, the server application must create its own local instance of these objects, because the caller's instance is in a separate process space. To handle this, Web Service applications create a data context for incoming requests. The data context persists while the server handles the request, and is freed after any output parameters are marshaled into a return message. When the server creates local instances of remotable objects, it adds them to the data context, and those instances are then freed along with the data context.

In some cases, you may want to keep an instance of a remotable object from being freed after a method call. For example, if the object contains state information, it may be more efficient to have a single instance that is used for every message call. To prevent the remotable object from being freed along with the data context, change its DataContext property.

Remotable Object Example (see page 2297)

3.2.5.4.6 Remotable Object Example

This example shows how to create a remotable object for a parameter on an invokable interface where you would otherwise use an existing class. In this example, the existing class is a string list (*TStringList*). To keep the example small, it does not reproduce the *Objects* property of the string list.

Because the new class is not scalar, it descends from *TRemotable* rather than *TRemotableXS*. It includes a published property for every property of the string list you want to communicate between the client and server. Each of these remotable properties corresponds to a remotable type. In addition, the new remotable class includes methods to convert to and from a string list.

```
TRemotableStringList = class(TRemotable)
```

```
  private
    FCaseSensitive: Boolean;
    FSorted: Boolean;
    FDuplicates: TDuplicates;
    FStrings: TStringDynArray;
  public
    procedure Assign(SourceList: TStringList);
    procedure AssignTo(DestList: TStringList);
  published
    property CaseSensitive: Boolean read FCaseSensitive write FCaseSensitive;
    property Sorted: Boolean read FSorted write FSorted;
    property Duplicates: TDuplicates read FDuplicates write FDuplicates;
    property Strings: TStringDynArray read FStrings write FStrings;
end;
class TRemotableStringList: public TRemotable
{
  private:
    bool FCaseSensitive;
    bool FSorted;
    Classes::TDuplicates FDuplicates;
    System::TStringDynArray FStrings;
  public:
    void __fastcall Assign(Classes::TStringList *SourceList);
    void __fastcall AssignTo(Classes::TStringList *DestList);
__published:
    __property bool CaseSensitive = {read=FCaseSensitive, write=FCaseSensitive};
    __property bool Sorted = {read=FSorted, write=FSorted};
    __property Classes::TDuplicates Duplicates = {read=FDuplicates, write=FDuplicates};
    __property System::TStringDynArray Strings = {read=FStrings, write=FStrings};
}
```

Note that *TRemotableStringList* exists only as a transport class. Thus, although it has a *Sorted* property (to transport the value of a string list's *Sorted* property), it does not need to sort the strings it stores, it only needs to record whether the strings should be sorted. This keeps the implementation very simple. You only need to implement the *Assign* and *AssignTo* methods, which convert to and from a string list:

```
procedure TRemotableStringList.Assign(SourceList: TStrings);
var I: Integer;
begin
  SetLength(Strings, SourceList.Count);
  for I := 0 to SourceList.Count - 1 do
    Strings[I] := SourceList[I];
  CaseSensitive := SourceList.CaseSensitive;
  Sorted := SourceList.Sorted;
  Duplicates := SourceList.Duplicates;
end;
procedure TRemotableStringList.AssignTo(DestList: TStrings);
var I: Integer;
begin
  DestList.Clear;
  DestList.Capacity := Length(Strings);
  DestList.CaseSensitive := CaseSensitive;
  DestList.Sorted := Sorted;
  DestList.Duplicates := Duplicates;
  for I := 0 to Length(Strings) - 1 do
    DestList.Add(Strings[I]);
end;
void __fastcall TRemotableStringList::Assign(Classes::TStringList *SourceList)
{
  SetLength(Strings, SourceList->Count);
  for (int i = 0; i < SourceList->Count; i++)
    Strings[i] = SourceList->Strings[i];
  CaseSensitive = SourceList->CaseSensitive;
  Sorted = SourceList->Sorted;
  Duplicates = SourceList->Duplicates;
}
```

```
void __fastcall TRemotableStringList::AssignTo(Classes::TStringList *DestList)
{
  DestList->Clear();
  DestList->Capacity = Length(Strings);
  DestList->CaseSensitive = CaseSensitive;
  DestList->Sorted = Sorted;
  DestList->Duplicates = Duplicates;
  for (int i = 0; i < Length(Strings); i++)
    DestList->Add(Strings[i]);
}
```

Optionally, you may want to register the new remotable class so that you can specify its class name. If you do not register the class, it is registered automatically when you register the interface that uses it. Similarly, if you register the class but not the *TDuplicates* and *TStringDynArray* types that it uses, they are registered automatically. This code shows how to register the *TRemotableStringList* class and the *TDuplicates* type. *TStringDynArray* is registered automatically because it is one of the built-in dynamic array types declared in the Types unit.

This registration code goes in the initialization section of the unit where you define the remotable class:

```
RemClassRegistry.RegisterXSInfo(TypeInfo(TDuplicates), MyNameSpace, 'duplicateFlag');
RemClassRegistry.RegisterXSClass(TRemotableStringList, MyNameSpace, 'stringList', '',False);
void RegTypes()
{
  RemTypeRegistry()->RegisterXSclass(__classid(TRemotableStringList), MyNameSpace,
"stringList", "", false);
}
#pragma startup initServices 32
```

3.2.5.4.7 Writing Servers that Support Web Services

In addition to the invokable interfaces and the classes that implement them, your server requires two components: a dispatcher and an invoker. The dispatcher (THTTPSoapDispatcher) receives incoming SOAP messages and passes them on to the invoker. The invoker (THTTPSOAPPascalInvoker) interprets the SOAP message, identifies the invokable interface it calls, executes the call, and assembles the response message.

Note: *THTTPSoapDispatcher* and*THTTPSoapPascalInvoker are designed to respond to HTTP messages containing a SOAP request. The underlying architecture is sufficiently general, however, that it can support other protocols with the substitution of different dispatcher and invoker components.*

Once you register your invokable interfaces and their implementation classes, the dispatcher and invoker automatically handle any messages that identify those interfaces in the SOAP Action header of the HTTP request message.

Web services also include a publisher (TWSDLHTMLPublish). Publishers respond to incoming client requests by creating the WSDL documents that describe how to call the Web Services in the application.

Building a Web Service server

RAD Studio provides a wizard to speed development of a Web Service server application.

Use the following steps to build a server application that implements a Web Service:

1. Choose **File** ▶ **New** ▶ **Other** and on the WebServices page, double-click the Soap Server Application icon to launch the SOAP Server Application wizard (see page 2300). The wizard creates a new Web server application that includes the components you need to respond to SOAP requests.
2. When you exit the SOAP Server Application wizard, it asks you if you want to define an interface for your Web Service. If you are creating a Web Service from scratch, click yes, and you will see the Add New Web Service wizard. The wizard adds code

to declare and register a new invokable interface for your Web Service. Edit the generated code to define and implement your Web Service. If you want to add additional interfaces (or you want to define the interfaces at a later time), choose **File** ▸ **New** ▸ **Other**, and on the WebServices page, double-click the SOAP Web Service interface icon. For details on using the Add New Web Service wizard and completing the code it generates, see Adding new Web Services (see page 2301).

3. If you are implementing a Web Service that has already been defined in a WSDL document, you can use the WSDL importer to generate the interfaces, implementation classes, and registration code that your application needs. You need only fill in the body of the methods the importer generates for the implementation classes. For details on using the WSDL importer, see Using the WSDL importer (see page 2302).
4. If you want to use the headers in the SOAP envelope that encodes messages between your application and clients, you can define classes to represent those headers and write code to process them. This is described in Defining and using SOAP headers (see page 2303).
5. If your application raises an exception when attempting to execute a SOAP request, the exception will be automatically encoded in a SOAP fault packet, which is returned instead of the results of the method call. If you want to convey more information than a simple error message, you can create your own exception classes that are encoded and passed to the client. This is described in Creating custom exception classes for Web Services (see page 2305).
6. The SOAP Server Application wizard adds a publisher component (*TWSDLHTMLPublish)* to new Web Service applications. This enables your application to publish WSDL documents that describe your Web Service to clients. For information on the WSDL publisher, see Generating WSDL documents for a Web Service application (see page 2306).

See Also

Understanding Invokable Interfaces (see page 2292)

3.2.5.4.8 Using the SOAP Application Wizard

Web Service applications are a special form of Web Server application. Because of this, support for Web Services is built on top of the Web Broker architecture. To understand the code that the SOAP Application wizard generates, therefore, it is helpful to understand the Web Broker architecture. Information about Web Server applications in general, and Web Broker in particular, can be found in Creating Internet server applications (see page 2251) and Using Web Broker (see page 2272).

To launch the SOAP application wizard, choose **File** ▸ **New** ▸ **Other**, and on the WebServices page, double-click the Soap Server Application icon. Choose the type of Web server application you want to use for your Web Service. For information about different types of Web Server applications, see Types of Web server applications (see page 2249).

The wizard generates a new Web server application that includes a Web module which contains three components:

- An invoker component (THTTPSOAPPascalInvoker). The invoker converts between SOAP messages and the methods of any registered invokable interfaces in your Web Service application.
- A dispatcher component (THTTPSoapDispatcher). The dispatcher automatically responds to incoming SOAP messages and forwards them to the invoker. You can use its *WebDispatch* property to identify the HTTP request messages to which your application responds. This involves setting the *PathInfo* property to indicate the path portion of any URL directed to your application, and the *MethodType* property to indicate the method header for request messages.
- A WSDL publisher (TWSDLHTMLPublish). The WSDL publisher publishes a WSDL document that describes your interfaces and how to call them. The WSDL document tells clients that how to call on your Web Service application. For details on using the WSDL publisher, see Generating WSDL documents for a Web Service application (see page 2306).

The SOAP dispatcher and WSDL publisher are auto-dispatching components. This means they automatically register themselves with the Web module so that it forwards any incoming requests addressed using the path information they specify in their *WebDispatch* properties. If you right-click on the Web module, you can see that in addition to these auto-dispatching components, it has a single Web action item named *DefaultHandler*.

DefaultHandler is the default action item. That is, if the Web module receives a request for which it can't find a handler (can't match the path information), it forwards that message to the default action item. *DefaultHandler* generates a Web page that describes your Web Service. To change the default action, edit this action item's *OnAction* event handler.

Creating Custom Exception Classes for Web Services (see page 2305)

Adding New Web Services (see page 2301)

Defining and Using SOAP Headers (see page 2303)

3.2.5.4.9 Adding New Web Services

To add a new Web Service interface to your server application, choose **File ▸ New ▸ Other**, and on the WebServices page double-click on the icon labeled SOAP Server Interface.

The Add New Web Service wizard lets you specify the name of the invokable interface you want to expose to clients, and generates the code to declare and register the interface and its implementation class. By default, the wizard also generates comments that show sample methods and additional type definitions, to help you get started in editing the generated files.

Editing the generated code

The interface definitions appear in the interface section of the generated unit. This generated unit has the name you specified using the wizard. You will want to change the interface declaration, replacing the sample methods with the methods you are making available to clients.

The wizard generates an implementation class that descends from TInvokableClass and that supports the invokable interface). If you are defining an invokable interface from scratch, you must edit the declaration of the implementation class to match any edits you made to the generated invokable interface.

When adding methods to the invokable interface and implementation class, remember that the methods must only use remotable types. For information on remotable types and invokable interfaces, see Using nonscalar types in invokable interfaces (see page 2293).

Using a different base class

The Add New WebService wizard generates implementation classes that descend from *TInvokableClass*. This is the easiest way to create a new class to implement a Web Service. You can, however, replace this generated class with an implementation class that has a different base class (for example, you may want to use an existing class as a base class.) There are a number of considerations to take into account when you replace the generated implementation class:

- Your new implementation class must support the invokable interface directly. The invocation registry, with which you register invokable interfaces and their implementation classes, keeps track of what class implements each registered interface and makes it available to the invoker component when the invoker needs to call the interface. It can only detect that a class implements an interface if the interface is directly included in the class declaration. It does not detect support an interface if it is inherited along with a base class.
- Your new implementation class must include support for the *IInterface* methods that are part of any interface. This point may seem obvious, but it is an easy one to overlook.
- You must change the generated code that registers the implementation class to include a factory method to create instances of your implementation class.

This last point takes a bit of explanation. When the implementation class descends from *TInvokableClass* and does not replace the inherited constructor with a new constructor that includes one or more parameters, the invocation registry knows how to create instances of the class when it needs them. When you write an implementation class that does not descend from *TInvokableClass*, or when you change the constructor, you must tell the invocation registry how to obtain instances of your implementation class.

You can tell the invocation registry how to obtain instances of your implementation class by supplying it with a factory procedure. Even if you have an implementation class that descends from *TInvokableClass* and that uses the inherited constructor, you may want to supply a factory procedure anyway. For example, you can use a single global instance of your implementation class rather than requiring the invocation registry to create a new instance every time your application receives a call to the invokable interface.

The factory procedure must be of type *TCreateInstanceProc*. It returns an instance of your implementation class. If the procedure creates a new instance, the implementation object should free itself when the reference count on its interface drops

to zero, as the invocation registry does not explicitly free object instances. The following code illustrates another approach, where the factory procedure returns a single global instance of the implementation class:

```
procedure CreateEncodeDecode(out obj: TObject);
begin
  if FEncodeDecode = nil then
  begin
    FEncodeDecode := TEncodeDecode.Create;
    {save a reference to the interface so that the global instance doesn't free itself }
    FEncodeDecodeInterface := FEncodeDecode as IEncodeDecode;
  end;
  obj := FEncodeDecode; { return global instance }
end;
void __fastcall CreateEncodeDecode(System::TObject* &obj)
{
  if (!FEncodeDecode)
  {
    FEncodeDecode = new TEncodeDecodeImpl();
    // save a reference to the interface so that the global instance doesn't free itself
    TEncodeDecodeImpl->QueryInterface(FEncodeDecodeInterface);
  }
  obj = FEncodeDecode;
}
```

Note: In this example, *FEncodeDecodeInterface* is a variable of type *IEncodeDecode*.

You register the factory procedure with an implementation class by supplying it as a second parameter to the call that registers the class with the invocation registry. First, locate the call the wizard generated to register the implementation class. This appears in initialization section of the unit that defines the class. It looks something like the following:

```
InvRegistry.RegisterInvokableClass(TEncodeDecode);
InvRegistry()->RegisterInvokableClass(__classid(TEncodeDecodeImpl));
```

Add a second parameter to this call that specifies the factory procedure:

```
InvRegistry.RegisterInvokableClass(TEncodeDecode, CreateEncodeDecode);
InvRegistry()->RegisterInvokableClass(__classid(TEncodeDecodeImpl), &CreateEncodeDecode);
```

Using the SOAP Application Wizard (see page 2300)

Understanding Invokable Interfaces (see page 2292)

Defining and Using SOAP Headers (see page 2303)

3.2.5.4.10 Using the WSDL Importer

To use the WSDL importer, choose File|New|Other, and on the WebServices page double-click the icon labeled WSDL importer. In the dialog that appears, specify the file name of a WSDL document (or XML file) or provide the URL where that document is published.

Note: If you do not know the URL for the WSDL document you want to import, you can browse for one by clicking the button labeled Search UDDI. This launches the UDDI browser.

Tip: An advantage of using the UDDI browser, even if you know the location of the WSDL document, is that when you locate the WSDL document using a UDDI description, client applications get fail-over support.

If the WSDL document is on a server that requires authentication (or must be reached using a proxy server that requires authentication), you need to provide a user name and password before the wizard can retrieve the WSDL document. To supply this information, click the Options button and provide the appropriate connection information.

When you click the Next button, the WSDL importer displays the code it generates for every definition in the WSDL document that is compatible with the Web Services framework. That is, it only uses those port types that have a SOAP binding. You can configure the way the importer generates code by clicking the Options button and choosing the options you want.

You can use the WSDL importer when writing either a server or a client application. When writing a server, click the Options button and in the resulting dialog, check the option that tells the importer to generate server code. When you select this option, the importer generates implementation classes for the invokable interfaces, and you need only fill in the bodies of the methods.

Warning: If you import a WSDL document to create a server that implements a Web Service that is already defined, you must still publish your own WSDL document for that service. There may be minor differences in the imported WSDL document and the generated implementation. For example, if the WSDL document or XML schema file uses identifiers that are also keywords, the importer automatically adjusts their names so that the generated code can compile.

When you click Finish, the importer creates new units that define and register invokable interfaces for the operations defined in the document, and that define and register remotable classes for the types that the document defines.

As an alternate approach, you can use the command line WSDL importer instead. For a server, call the command line importer with the -Os option, as follows:

```
WSDLIMP -Os -P -V MyWSDLDoc.wsdl
WSDLIMP -Os -C -V MyWSDLDoc.wsdl
```

For a client application, call the command line importer without the -Os option:

```
WSDLIMP -P -V MyWSDLDoc.wsdl
WSDLIMP -C -V MyWSDLDoc.wsdl
```

Tip: The command line interpreter includes some options that are not available when you use the WSDL importer in the IDE. For details, see the help for WSDLIMP.

Defining and Using SOAP Headers (see page 2303)

WSDLIMP.EXE (see page 214)

3.2.5.4.11 Defining and Using SOAP Headers

The SOAP encoding of a request to your Web Service application and of the response your application sends include a set of header nodes. Some of these, such as the SOAP Action header, are generated and interpreted automatically. However, you can also define your own headers to customize the communication between your server and its clients. Typically, these headers contain information that is associated with the entire invokable interface, or even with the entire application, rather than just the method that is the subject of a single message.

Defining header classes

For each header you want to define, create a descendant of TSOAPHeader. *TSOAPHeader* is a descendant of *TRemotable*. That is, SOAP header objects are simply special types of remotable objects (see page 2296). As with any remotable object, you can add published properties to your *TSOAPHeader* descendant to represent the information that your header

communicates. Once you have defined a SOAP header class, it must be registered with the remotable type registry (see page 2294). Note that unlike other remotable classes, which are registered automatically when you register an invokable interface that uses them, you must explicitly write code to register your header types.

TSOAPHeader defines two properties that are used to represent attributes of the SOAP header node. These are *MustUnderstand* and *Actor*. When the *MustUnderstand* attribute is *True*, the recipient of a message that includes the header is required to recognize it. If the recipient can't interpret a header with the *MustUnderstand* attribute, it must abort the interpretation of the entire message. An application can safely ignore any headers it does not recognize if their *MustUnderstand* attribute is not set. The use of *MustUnderstand* is qualified by the *Actor* property. *Actor* is a URI that identifies the application to which the header is directed. Thus, for example, if your Web Service application forwards requests on to another service for further processing, some of the headers in client messages may be targeted at that other service. If such a header includes the *MustUnderstand* attribute, you should not abort the request even if your application can't understand the header. Your application is only concerned with those headers that give its URL as the *Actor*.

Sending and receiving headers

Once you have defined and registered header classes, they are available for your application to use. When your application receives a request, the headers on that message are automatically converted into the corresponding *TSOAPHeader* descendants that you have defined. Your application identifies the appropriate header class by matching the name of the header node against the type name you used when you registered the header class or against a name you supply by registering the header class with the invocation registry. Any headers for which the application can't find a match in the remotable type registry are ignored (or, if their *MustUnderstand* attribute is *True*, the application generates a SOAP fault).

You can access the headers your application receives using the ISOAPHeaders interface. There are two ways to obtain this interface: from an instance of *TInvokableClass* or, if you are implementing your invokable interface without using *TInvokableClass*, by calling the global GetSOAPHeaders function.

Use the *Get* method of *ISOAPHeaders* to access the headers by name. For example:

```
TServiceImpl.GetQuote(Symbol: string): Double;
var
  Headers: ISOAPHeaders;
  H: TAuthHeader;
begin
  Headers := Self as ISOAPHeaders;
  Headers.Get(AuthHeader, TSOAPHeader(H)); { Retrieve the authentication header }
  try
    if H = nil then
      raise ERemotableException.Create("SOAP header for authentication required");
    { code here to check name and password }
  finally
    H.Free;
  end;
  { now that user is authenticated, look up and return quote }
end;
```

If you want to include any headers in the response your application generates to a request message, you can use the same interface. *ISOAPHeaders* defines a *Send* method to add headers to the outgoing response. Simply create an instance of each header class that corresponds to a header you want to send, set its properties, and call *Send*:

```
TServiceImpl.GetQuote(Symbol: string): Double;
var
  Headers: ISOAPHeaders;
  H: TQuoteDelay;
  TXSDuration Delay;
begin
  Headers := Self as ISOAPHeaders;
  { code to lookup the quote and set the return value }
  { this code sets the Delay variable to the time delay on the quote }
  H := TQuoteDelay.Create;
  H.Delay := Delay;
  Headers.OwnsSentHeaders := True;
```

```
  Headers.Send(H);
end;
```

Handling scalar-type headers

Some Web Services define and use headers that are simple types (such as an integer or string) rather than a complex structure that corresponds to a remotable type. However, Delphi's support for SOAP headers requires that you use a *TSOAPHeader* descendant to represent header types. You can define header classes for simple types by treating the *TSOAPHeader* class as a holder class. That is, the *TSOAPHeader* descendant has a single published property, which is the type of the actual header. To signal that the SOAP representation does not need to include a node for the *TSOAPHeader* descendant, call the remotable type registry's RegisterSerializeOptions method (after registering the header type) and give your header type an option of *xoSimpleTypeWrapper*.

Communicating the structure of your headers to other applications

If your application defines headers, you need to allow its clients to access those definitions. If those clients are also written in Delphi, you can share the unit that defines and registers your header classes with the client application. However, you may want to let other clients know about the headers you use as well. To enable your application to export information about its header classes, you must register them with the invocation registry. Registering a header class also associates that class with a header name that is defined within a namespace.

Like the code that registers your invokable interface, the code to register a header class for export is added to the initialization section of the unit in which it is defined. Use the global *InvRegistry* function to obtain a reference to the invocation registry and call its *RegisterHeaderClass* method, indicating the interface with which the header is associated:

```
initialization
  InvRegistry.RegisterInterface(TypeInfo(IMyWebService)); {register the interface}
  InvRegistry.RegisterHeaderClass(TypeInfo(IMyWebService), TMyHeaderClass); {and the header}
end.
static void RegTypes()
{
  // register the invokable interface:
  InvRegistry()->RegisterInterface(__delphirtti(IMyService), "", "");
// register the header to be used with it:
  InvRegistry()->RegisterHeaderClass(__delphirtti(IMyService), __classid(TMyHeader));
}
#pragma startup RegTypes 32
```

You can limit the header to a subset of the methods on the interface by subsequent calls to the *RegisterHeaderMethod* method.

Note: The implementation section's uses clause must include the InvokeRegistry unit so that the call to the *InvRegistry* function is defined.

Once you have registered your header class with the invocation registry, its description is added to WSDL documents when you publish your Web Service (see page 2306).

Note: This registration of your header class with the invocation registry is in addition to the registration of that class with the remotable type registry.

Using Nonscalar Types in Invokable Interfaces (see page 2293)

Generating WSDL Documents for a Web Service Application (see page 2306)

Creating Custom Exception Classes for Web Services (see page 2305)

Processing Headers in Client Applications (see page 2310)

3.2.5.4.12 Creating Custom Exception Classes for Web Services

When your Web Service application raises an exception in the course of trying to execute a SOAP request, it automatically

encodes information about that exception in a SOAP fault packet, which it returns instead of the results of the method call. The client application then raises the exception.

By default, the client application raises a generic exception of type ERemotableException with the information from the SOAP fault packet. You can transmit additional, application-specific information by deriving an ERemotableException descendant. The values of any published properties you add to the exception class are included in the SOAP fault packet so that the client can raise an equivalent exception.

To use an *ERemotableException* descendant, you must register it with the remotable type registry. Thus, in the unit that defines your *ERemotableException* descendant, you must add the InvokeRegistry unit to the uses clause and add a call to the RegisterXSClass method of the object that the global *RemTypeRegistry* function returns.

If the client also defines and registers your *ERemotableException* descendant, then when it receives the SOAP fault packet, it automatically raises an instance of the appropriate exception class, with all properties set to the values in the SOAP fault packet.

To allow clients to import information about your *ERemotableException* descendant, you must register it with the invocation registry as well as the remotable type registry. Add a call to the RegisterException method of the object that the global *InvRegistry* function returns.

Using Nonscalar Types in Invokable Interfaces (see page 2293)

Generating WSDL Documents for a Web Service Application (see page 2306)

Defining and Using SOAP Headers (see page 2303)

3.2.5.4.13 Generating WSDL Documents for a Web Service Application

To allow client applications to know what Web Services your application makes available, you can publish a WSDL document that describes your invokable interfaces and indicates how to call them.

To publish a WSDL document that describes your Web Service, include a TWSDLHTMLPublish component in your Web Module. (The SOAP Server Application wizard adds this component by default.) *TWSDLHTMLPublish* is an auto-dispatching component, which means it automatically responds to incoming messages that request a list of WSDL documents for your Web Service. Use the WebDispatch property to specify the path information of the URL that clients must use to access the list of WSDL documents. The Web browser can then request the list of WSDL documents by specifying an URL that is made up of the location of the server application followed by the path in the *WebDispatch* property. This URL looks something like the following:

```
http://www.myco.com/MyService.dll/WSDL
```

Tip: If you want to use a physical WSDL file instead, you can display the WSDL document in your Web browser and then save it to generate a WSDL document file.

Note: In addition to the WSDL document, the *THWSDLHTMLPublish* also generates a WS-Inspection document to describe the service for automated tools. The URL for this document looks something like the following:

```
http://www.myco.com/MyService.dll/inspection.wsil
```

It is not necessary to publish the WSDL document from the same application that implements your Web Service. To create an application that simply publishes the WSDL document, omit the code that implements and registers the implementation objects and only include the code that defines and registers invokable interfaces, remotable classes that represent complex types, and any remotable exceptions.

By default, when you publish a WSDL document, it indicates that the services are available at the same URL as the one where you published the WSDL document (but with a different path). If you are deploying multiple versions of your Web Service

application, or if you are publishing the WSDL document from a different application than the one that implements the Web Service, you will need to change the WSDL document so that it includes updated information on where to locate the Web Service.

To change the URL, use the WSDL administrator. The first step is to enable the administrator. You do this by setting the AdminEnabled property of the *TWSDLHTMLPublish* component to true. Then, when you use your browser to display the list of WSDL documents, it includes a button to administer them as well. Use the WSDL administrator to specify the locations (URLs) where you have deployed your Web Service application.

Creating Custom Exception Classes for Web Services (see page 2305)

Defining and Using SOAP Headers (see page 2303)

3.2.5.4.14 Writing Clients for Web Services

You can write clients that access Web Services that you have written, or any other Web Service that is defined in a WSDL document. There are three steps to writing an application that is the client of a Web Service:

- Importing the definitions from a WSDL document (see page 2307).
- Obtaining an invokable interface and calling it to invoke the Web Service (see page 2307).
- Processing the headers of the SOAP messages that pass between the client and the server (see page 2310).

See Also

Creating Custom Exception Classes for Web Services (see page 2305)

3.2.5.4.15 Importing WSDL Documents

Before you can use a Web Service, your application must define and register the invokable interfaces and types that are included in the Web Service application. To obtain these definitions, you can import a WSDL document (see page 2302) (or XML file) that defines the service. The WSDL importer creates a unit that defines and registers the interfaces, headers, and types you need to use.

See Also

Calling Invokable Interfaces (see page 2307)

Processing Headers in Client Applications (see page 2310)

3.2.5.4.16 Calling Invokable Interfaces

To call an invokable interface, your client application must include any definitions of the invokable interfaces and any remotable classes that implement complex types.

If the server is written in Delphi or C++Builder, you can use the same units that the server application uses to define and register these interfaces and classes instead of the files generated by importing a WSDL file. Be sure that the unit uses the same namespace URI and SOAPAction header when it registers invokable interfaces. These values can be explicitly specified in the code that registers the interfaces, or it can be automatically generated. If it is automatically generated, the unit that defines the interfaces must have the same name in both client and server, and both client and server must define the global *AppNameSpacePrefix* variable to have the same value.

Once you have the definition of the invokable interface, there are two ways you can obtain an instance to call:

- If you imported a WSDL document, the importer automatically generates a global function that returns the interface, which you can then call.
- You can use a remote interfaced object.

Obtaining an invokable interface from the generated function

The WSDL importer automatically generates a function from which you can obtain the invokable interfaces you imported. For example, if you imported a WSDL document that defined an invokable interface named *IServerInterface*, the generated unit would include the following global function:

```
function GetIServerInterface(UseWSDL: Boolean; Addr: string; HTTPRIO: THTTPRIO):
IServerInterface;
_di_IServerInterface GetIServerInterface(bool UseWSDL, AnsiString Addr, THTTPRIO* HTTPRIO);
```

The generated function takes three parameters: *UseWSDL*, *Addr*, and *HTTPRio*. *UseWSDL* indicates whether to look up the location of the server from a WSDL document (true), or whether the client application supplies the URL for the server (false).

When *UseWSDL* is false, *Addr* is the URL for the Web Service. When *UseWSDL* is true, *Addr* is the URL of a WSDL document that describes the Web Service you are calling. If you supply an empty string, this defaults to the document you imported. This second approach is best if you expect that the URL for the Web Service may change, or that details such as the namespace or SOAP Action header may change. Using this second approach, this information is looked up dynamically at the time your application makes the method call.

Note: For performance reasons, it is best to use a URL instead of a WSDL parameter. For WSDL, the SOAP runtime must perform an `HTTP GET` for the WSDL parameter before invoking a Web Service operation. The *HTTPRio* parameter specifies the Remotable Interface Object to be used to obtain the interface. If you specify a value of NULL for the *HTTPRio* parameter, the method creates a new *THTTPRio* instance. You can specify the *THTTPRio* instance if you want to use the Object Inspector to customize the object and handle events.

Note: The generated function uses an internal remote interfaced object to implement the invokable interface. If you are using this function and find you need to access that underlying remote interfaced object, you can obtain an *IRIOAccess* interface from the invokable interface, and use that to access the remote interfaced object:

```
var
  Interf: IServerInterface;
  RIOAccess: IRIOAccess;
  X: THTTPRIO;
begin
  Intrf := GetIServerInterface(True,
          'http://MyServices.org/scripts/AppServer.dll/wsdl');
  RIOAccess := Intrf as IRIOAccess;
  X := RIOAccess.RIO as THTTPRIO;
_di_EchoUnboundedSoap service = GetEchoUnboundedSoap();
 _di_IRIOAccess rioAccess = service;
 TSOAPConvertOptions options = rioAccess->GetRIO()->Converter->GetOptions();
```

Using a remote interfaced object

If you do not use the global function to obtain the invokable interface you want to call, you can create an instance of THTTPRio for the desired interface:

```
X := THTTPRio.Create(nil);
X = new THTTPRio(NULL);
```

Note: It is important that you do not explicitly destroy the *THTTPRio* instance. If it is created without an *Owner* (as in the previous line of code), it automatically frees itself when its interface is released. If it is created with an *Owner*, the *Owner* is responsible for freeing the *THTTPRio* instance.

Once you have an instance of *THTTPRio*, provide it with the information it needs to identify the server interface and locate the server. There are two ways to supply this information:

If you do not expect the URL for the Web Service or the namespaces and soap Action headers it requires to change, you can simply specify the URL for the Web Service you want to access. *THTTPRio* uses this URL to look up the definition of the interface, plus any namespace and header information, based on the information in the invocation registry. Specify the URL by setting the *URL* property to the location of the server:

```
X.URL := 'http://www.myco.com/MyService.dll/SOAP/IServerInterface';
```

If you want to look up the URL, namespace, or Soap Action header from the WSDL document dynamically at runtime, you can use the *WSDLLocation*, *Service*, and *Port* properties, and it will extract the necessary information from the WSDL document:

```
X.WSDLLocation := 'Cryptography.wsdl';
X.Service := 'Cryptography';
X.Port := 'SoapEncodeDecode';
```

After specifying how to locate the server and identify the interface, you can obtain an interface pointer for the invokable interface from the *THTTPRio* object. You obtain this interface pointer using the as operator. Simply cast the *THTTPRio* instance to the invokable interface:

```
InterfaceVariable := X as IEncodeDecode;
Code := InterfaceVariable.EncodeValue(5);
_di_IEncodeDecode InterfaceVariable;
if (X->QueryInterface(InterfaceVariable) == S_OK)
{
  Code = InterfaceVariable->EncodeValue(5);
}
```

When you obtain the interface pointer, *THTTPRio* creates a vtable for the associated interface dynamically in memory, enabling you to make interface calls.

THTTPRio relies on the invocation registry to obtain information about the invokable interface. If the client application does not have an invocation registry, or if the invokable interface is not registered, *THTTPRio* can't build its in-memory vtable.

Warning: If you assign the interface you obtain from *THTTPRio* to a global variable, you must change that assignment to nil before shutting down your application. For example, if *InterfaceVariable* in the previous code sample is a global variable, rather than stack variable, you must release the interface before the *THTTPRio* object is freed. Typically, this code goes in the *OnDestroy* event handler of the form or data module:

```
procedure TForm1.FormDestroy(Sender: TObject);
begin
  InterfaceVariable := nil;
end;
void __fastcall TForm1::FormDestroy(TObject *Sender)
{
  InterfaceVariable = NULL;
}
```

The reason you must reassign a global interface variable to nil is because *THTTPRio* builds its vtable dynamically in memory. That vtable must still be present when the interface is released. If you do not release the interface along with the form or data module, it is released when the global variable is freed on shutdown. The memory for global variables may be freed after the form or data module that contains the *THTTPRio* object, in which case the vtable will not be available when the interface is released.

Importing WSDL Documents (see page 2307)

Processing Headers in Client Applications (see page 2310)

3.2.5.4.17 Processing Headers in Client Applications

If the Web Service application you are calling expects your client to include any headers in its requests or if its response messages include special headers, your client application needs the definitions of the header classes that correspond to these headers. When you import a WSDL document that describes the Web Service application, the importer automatically generates code to declare these header classes and register them with the remotable type registry. If the server is written in Delphi, you can use the same units that the server application uses to define and register these header classes instead of the files generated by importing a WSDL file. Be sure that the unit uses the same namespace URI and SOAPAction header when it registers invokable interfaces. These values can be explicitly specified in the code that registers the interfaces, or it can be automatically generated. If it is automatically generated, the unit that defines the interfaces must have the same name in both client and server, and both client and server must define the global *AppSpacePrefix* variable to have the same value.

Note: For more information about header classes, see Defining and using SOAP headers (see page 2303).

As with a server, client applications use the ISOAPHeaders interface to access incoming headers and add outgoing headers. The remote interfaced object that you use to call invokable interfaces implements the *ISOAPHeaders* interface. However, you can't obtain an *ISOAPHeaders* interface directly from the remote interfaced object. This is because when you try to obtain an interface directly from a remote interfaced object, it generates an in-memory vtable, assuming that the interface is an invokable interface. Thus, you must obtain the *ISOAPHeaders* interface from the invokable interface rather than from the remote interfaced object:

```
var
  Service: IMyService;
  Hdr: TAuthHeader;
  Val: Double;
begin
  Service := HTTPRIO1 as IService;
  Hdr := TAUthHeader.Create;
  try
    Hdr.Name := "Frank Borland";
    Hdr.Password := "SuperDelphi";
    (Service as ISOAPHeaders).Send(Hdr); { add the header to outgoing message }
    Val := Service.GetQuote("BORL"); { invoke the service }
  finally
    Hdr.Free;
  end;
end;
```

3.2.5.5.1.1 Advanced HTML Design

Using adapters and adapter page producers, WebSnap makes it easy to create scripted HTML pages in your Web server application. You can create a Web front end for your application data using WebSnap tools that may suit all of your needs. One

powerful feature of WebSnap, however, is the ability to incorporate Web design expertise from other sources into your application. This section discusses some strategies for expanding the Web server design and maintenance process to include other tools and non-programmer team members.

The end products of WebSnap development are your server application and HTML templates for the pages that the server produces. The templates include a mixture of scripting and HTML. Once they have been generated initially, they can be edited at any time using any HTML tool you like. (It would be best to use a tool that supports embedded script tags, like Microsoft FrontPage, to ensure that the editor doesn't accidentally damage the script.) The ability to edit template pages outside of the IDE can be used many ways.

After the product has been deployed, you may wish to change the look of the final HTML pages. Perhaps your software development team is not even responsible for the final page layout. That duty may belong to a dedicated Web page designer in your organization, for example. Your page designers may not have any experience with software development. Fortunately, they don't have to. They can edit the page templates at any point in the product development and maintenance cycle, without ever changing the source code. Thus, WebSnap HTML templates can make server development and maintenance more efficient.

Manipulating server-side script in HTML files

HTML in page templates can be modified at any time in the development cycle. Server-side scripting can be a different matter, however. It is always possible to manipulate the server-side script in the templates outside of the IDE, but it is not recommended for pages generated by an adapter page producer. The adapter page producer is different from ordinary page producers in that it can change the server-side scripting in the page templates at runtime. It can be difficult to predict how your script will act if other script is added dynamically. If you want to manipulate script directly, make sure that your Web page module contains a page producer instead of an adapter page producer.

If you have a Web page module that uses an adapter page producer, you can convert it to use a regular page producer instead by using the following steps.

To modify a Web page module to use a regular page producer

1. You can access the page module view with server-side scripting using the HTML Script tab. In the module you want to convert (let's call it ModuleName), copy all of the information from the HTML Script tab to the ModuleName.html tab, replacing all of the information that it contained previously.

   Note: When the Web Page module uses *TAdapterPageProducer* the page module views become available when this component is double-clicked .

2. Drop a page producer (located on the Internet category of the **Tool Palette**) onto your Web page module.
3. Set the page producer's ScriptEngine property to match that of the adapter page producer it replaces.
4. Change the page producer in the Web page module from the adapter page producer to the new page producer.
5. The adapter page producer has now been bypassed. You may now delete it from the Web page module.

3.2.5.5.1.2 Specifying Application Module Components

Application components provide the Web application's functionality. For example, including an adapter dispatcher component automatically handles HTML form submissions and the return of dynamically generated images. Including a page dispatcher automatically displays the content of a page when the HTTP request pathinfo contains the name of the page.

For information on creating web server applications, see Creating Web Server Applications with WebSnap (see page 2313).

Selecting the Components button on the new WebSnap application dialog displays another dialog that allows you to select one or more of the Web application module components.

The following table contains a brief explanation of the available components:

Web application components

Component type	Description
Application Adapter	Contains information about the application, such as the title. The default type is *TApplicationAdapter*.
End User Adapter	Contains information about the user, such as their name, access rights, and whether they are logged in. The default type is *TEndUserAdapter*. *TEndUserSessionAdapter* may also be selected.
Page Dispatcher	Examines the HTTP request's pathinfo and calls the appropriate page module to return the content of a page. The default type is *TPageDispatcher*.
Adapter Dispatcher	Automatically handles HTML form submissions and requests for dynamic images by calling adapter action and field components. The default type is *TAdapterDispatcher*.
Dispatch Actions	Allows you to define a collection of action items to handle requests based on pathinfo and method type. Action items call user-defined events or request the content of page-producer components. The default type is *TWebDispatcher*.
Locate File Service	Provides control over the loading of template files, and script include files, when the Web application is running. The default type is *TLocateFileService*.
Sessions Service	Stores information about end users that is needed for a short period of time. For example, you can use sessions to keep track of logged-in users and to automatically log a user out after a period of inactivity. The default type is *TSessionsService*.
User List Service	Keeps track of authorized users, their passwords, and their access rights. The default type is *TWebUserList*.

For each of the above components, the component types listed are the default types shipped with the IDE. Users can create their own component types or use third-party component types.

For information about modifying application module components, see Selecting Web Application Module Options (see page 2314).

3.2.5.5.1.3 Creating Web Server Applications with WebSnap

If you look at the source code for WebSnap, you will discover that WebSnap comprises hundreds of objects. In fact, WebSnap is so rich in objects and features that you could spend a long time studying its architecture in detail before understanding it completely. Fortunately, you really don't need to understand the whole WebSnap system before you start developing your server application.

Here you will learn more about how WebSnap works by creating a new Web server application.

To create a new Web server application using the WebSnap architecture:

1. Choose **File** ▶ **New** ▶ **Other**, and select the WebSnap folder from Delphi Projects.
2. In the right pane of the New Items window choose WebSnap Application. A dialog box appears (as shown below)
3. Specify the correct server type (see page 2314).
4. Use the components button to specify application module components (see page 2312).
5. Use the Page Options button to select application module options (see page 2314).

For further information about adding application module components, see Specifying Application Module Components (see page 2312).

See Also

Types of Web Server Applications (see page 2249)

The Structure of a Web Broker Application (see page 2286)

3.2.5.5.1.4 Selecting a Server Type

Select one of the following types of Web server application, depending on your application's type of Web server.

Web server application types

Server type	Description
ISAPI and NSAPI	Sets up your project as a DLL with the exported methods expected by the Web server.
Apache	Sets up your project as a DLL with the exported methods expected by the appropriate Apache Web server. Both Apache 1 and 2 are supported.
CGI stand-alone	Sets up your project as a console application which conforms to the Common Gateway Interface (CGI) standard.
Web App Debugger executable	Creates an environment for developing and testing Web server applications. This type of application is not intended for deployment.

See Also

Types of Web Server Applications (see page 2249)

The Structure of a Web Broker Application (see page 2286)

3.2.5.5.1.5 Selecting Web Application Module Options

If the selected application module type is a page module, you can associate a name with the page by entering a name in the Page Name field in the New WebSnap Application dialog box. At runtime, the instance of this module can be either kept in cache or removed from memory when the request has been serviced. Select either of the options from the Caching field. You can select more page module options by choosing the Page Options button.

For information on adding application module components, see Specifying Application Module Components (see page 2312).

The Application Module Page Options dialog is displayed and provides the following categories:

Note: The *AdapterPageProducer* supports only JScript.

- Producer: The producer type for the page can be set to one of *AdapterPageProducer*, *DataSetPageProducer*, *InetXPageProducer*, *PageProducer*, or *XSLPageProducer*. If the selected page producer supports scripting, then use the Script Engine drop-down list to select the language used to script the page.
- HTML: When the selected producer uses an HTML template this group will be visible.
- XSL: When the selected producer uses an XSL template, such as *TXSLPageProducer*, this group will be visible.
- New File: Check New File if you want a template file to be created and managed as part of the unit. A managed template file appears in the **Project Manager** and has the same file name and location as the unit source file. Uncheck New File if you want to use the properties of the producer component (typically the *HTMLDoc* or *HTMLFile* property).
- Template: When New File is checked, choose the default content for the template file from the Template drop-down. The standard template displays the title of the application, the title of the page, and hyperlinks to published pages. The blank template creates a blank page.
- Page: Enter a page name and title for the page module. The page name is used to reference the page in an HTTP request or within the application's logic, whereas the title is the name that the end user will see when the page is displayed in a browser.

- Published: Check Published to allow the page to automatically respond to HTTP requests where the page name matches the pathinfo in the request message.
- Login Required: Check Login Required to require the user to log on before the page can be accessed.

3.2.5.5.2 Creating Web Server Applications Using WebSnap

WebSnap augments Web Broker with additional components, wizards, and views—making it easier to build Web server applications that deliver complex, data-driven Web pages. WebSnap's support for multiple modules and for server-side scripting makes development and maintenance easier for teams of developers and Web designers.

WebSnap allows HTML design experts on your team to make a more effective contribution to Web server development and maintenance. The final product of the WebSnap development process includes a series of scriptable HTML page templates. These pages can be changed using HTML editors that support embedded script tags, like Microsoft FrontPage, or even a simple text editor. Changes can be made to the templates as needed, even after the application is deployed. There is no need to modify the project source code at all, which saves valuable development time. Also, WebSnap's multiple module support can be used to partition your application into smaller pieces during the coding phases of your project. Developers can work more independently.

The dispatcher components automatically handle requests for page content, HTML form submissions, and requests for dynamic images. WebSnap components called adapters provide a means to define a scriptable interface to the business rules of your application. For example, the *TDataSetAdapter* object is used to make dataset components scriptable. You can use WebSnap producer components to quickly build complex, data-driven forms and tables, or to use XSL to generate a page. You can use the session component to keep track of end users. You can use the user list component to provide access to user names, passwords, and access rights.

The Web application wizard allows you to quickly build an application that is customized with the components that you will need. The Web page module wizard allows you to create a module that defines a new page in your application. Or use the Web data module wizard to create a container for components that are shared across your Web application.

When the Web Page module uses *TAdapterPageProducer* the page module views become available when this component is double-clicked . The page module views show the result of server-side scripting without running the application. You can view the generated HTML in text form using the HTML Result tab. The HTML Script tab shows the page with server-side scripting, which is used to generate HTML for the page.

The following topics explain how to use the WebSnap components to create a Web server application:

- Fundamental WebSnap components (see page 2326)
- Creating Web Server Applications (see page 2313)
- Server-side scripting in WebSnap (see page 2333)
- Dispatching requests (see page 2320)

Note: WebSnap is being deprecated in RAD Studio. Although WebSnap is still documented in the online help, the WebSnap product is no longer fully supported. As an alternative, you should begin using IntraWeb (VCL for the Web). IntraWeb (see page 2254) is documented in this online help. For more documentation on VCL for the Web, go to http://www.atozed.com/intraweb/docs/.

3.2.5.5.3 Dispatching requests and responses

Topics

Name	Description
Adapter dispatcher operation (see page 2316)	
Dispatcher Components (see page 2319)	The dispatcher components in the Web application module control the flow of the application. The dispatchers determine how to handle certain types of HTTP request messages by examining the HTTP request. The adapter dispatcher component (*TAdapterDispatcher*) looks for a content field, or a query field, that identifies an adapter action component or an adapter image field component. If the adapter dispatcher finds a component, it passes control to that component. The Web dispatcher component (*TWebDispatcher*) maintains a collection of action items (of type *TWebActionItem*) that know how to handle certain types of HTTP request messages.... more (see page 2319)
Dispatching Action Items (see page 2320)	When responding to a request, the Web dispatcher (*TWebDispatcher*) searches through its list of action items for one that: • matches the PathInfo portion of the target URL's request message, and • can provide the service specified as the method of the request message. It accomplishes this by comparing the *PathInfo* and *MethodType* properties of the *TWebRequest* object with the properties of the same name on the action item. When the dispatcher finds the appropriate action item, it causes that action item to fire. When the action item fires, it does one of the following: • Fills in the response content... more (see page 2320)
Dispatching Requests and Responses (see page 2320)	One reason to use WebSnap for your Web server application development is that WebSnap components automatically handle HTML requests and responses. Instead of writing event handlers for common page transfer chores, you can focus your efforts on your business logic and server design. Still, it can be helpful to understand how WebSnap applications handle HTML requests and responses. This section gives you an overview of that process. Before handling any requests, the Web application module initializes the Web context object (of type TWebContext). The Web context object, which is accessed by calling the global WebContext function, provides global access to... more (see page 2320)
Page dispatcher operation (see page 2321)	When the page dispatcher receives a client request, it determines the page name by checking the PathInfo portion of the target URL's request message. If the PathInfo portion is not blank, the page dispatcher uses the ending word of PathInfo as the page name. If the PathInfo portion is blank, the page dispatcher tries to determine a default page name. If the page dispatcher's *DefaultPage* property contains a page name, the page dispatcher uses this name as the default page name. If the *DefaultPage* property is blank and the Web application module is a page module, the page dispatcher uses... more (see page 2321)

3.2.5.5.3.1 Adapter dispatcher operation

Topics

Name	Description
Adapter Dispatcher Operation (see page 2317)	The adapter dispatcher component (*TAdapterDispatcher*) automatically handles HTML form submissions, and requests for dynamic images, by calling adapter action and field components.

Receiving Adapter Requests and Generating Responses (see page 2318)	When the adapter dispatcher receives a client request, the adapter dispatcher creates adapter request and adapter response objects to hold information about that HTTP request. The adapter request and adapter response objects are stored in the Web context to allow access during the processing of the request. The adapter dispatcher creates two types of adapter request objects: action and image. It creates the action request object when executing an adapter action. It creates the image request object when retrieving an image from an adapter field. The adapter response object is used by the adapter component to indicate the response to... more (see page 2318)

3.2.5.5.3.1.1 Adapter Dispatcher Operation

The adapter dispatcher component (*TAdapterDispatcher*) automatically handles HTML form submissions, and requests for dynamic images, by calling adapter action and field components.

Using adapter components to generate content

For WebSnap applications to automatically execute adapter actions and retrieve dynamic images from adapter fields, the HTML content must be properly constructed. If the HTML content is not properly constructed, the resulting HTTP request will not contain the information that the adapter dispatcher needs to call adapter action and field components.

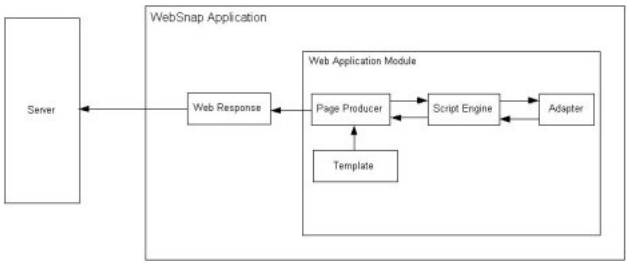
To reduce errors in constructing the HTML page, adapter components indicate the names and values of HTML elements. Adapter components have methods that retrieve the names and values of hidden fields that must appear on an HTML form designed to update adapter fields. Typically, page producers use server-side scripting to retrieve names and values from adapter components and then uses this information to generate HTML. For example, the following script constructs an <IMG> element that references the field called Graphic from Adapter1:

```
<img src="<%=Adapter1.Graphic.Image.AsHREF%>" alt="<%=Adapter1.Graphic.DisplayText%>">
```

When the Web application evaluates the script, the HTML src attribute will contain the information necessary to identify the field and any parameters that the field component needs to retrieve the image. The resulting HTML might look like this:

```
<img src="?_lSpecies No=90090&__id=DM.Adapter1.Graphic" alt="(GRAPHIC)">
```

When the browser sends an HTTP request to retrieve this image to the Web application, the adapter dispatcher will be able to determine that the Graphic field of Adapter1, in the module DM, should be called with "Species No=90090" as a parameter. The adapter dispatcher will call the Graphic field to write an appropriate HTTP response.



The following script constructs an <A> element referencing the EditRow action of Adapter1 and creates a hyperlink to a page called Details:

```
<a href="<%=Adapter1.EditRow.LinkToPage("Details", Page.Name).AsHREF%>">Edit...</a>
```

The resulting HTML might look like this:

```
<a href="?&_lSpecies No=90310&__sp=Edit&__fp=Grid&__id=DM.Adapter1.EditRow">Edit...</a>
```

The end user clicks this hyperlink, and the browser sends an HTTP request. The adapter dispatcher can determine that the EditRow action of Adapter1, in the module DM, should be called with the parameter Species No=903010. The adapter dispatcher also displays the Edit page if the action executes successfully, and displays the Grid page if action execution fails. It then calls the EditRow action to locate the row to be edited, and the page named Edit is called to generate an HTTP response. The following figure shows how adapter components are used to generate content.

The Structure of a Web Broker Application (see page 2286)

3.2.5.5.3.1.2 Receiving Adapter Requests and Generating Responses

When the adapter dispatcher receives a client request, the adapter dispatcher creates adapter request and adapter response objects to hold information about that HTTP request. The adapter request and adapter response objects are stored in the Web context to allow access during the processing of the request.

The adapter dispatcher creates two types of adapter request objects: action and image. It creates the action request object when executing an adapter action. It creates the image request object when retrieving an image from an adapter field.

The adapter response object is used by the adapter component to indicate the response to an adapter action or adapter image request. There are two types of adapter response objects, action and image.

Action requests

Action request objects are responsible for breaking the HTTP request down into information needed to execute an adapter action. The types of information needed for executing an adapter action may include the following request information:

Request information found in action requests

Request informaton	Description
Component name	Identifies the adapter action component.
Adapter mode	Defines a mode. For example, TDataSetAdapter supports Edit, Insert, and Browse modes. An adapter action may execute differently depending on the mode.
Success page	Identifies the page displayed after successful execution of the action.
Failure page	Identifies the page displayed if an error occurs during execution of the action.
Action request parameters	Identifies the parameters need by the adapter action. For example, the TDataSetAdapter Apply action will include the key values identifying the record to be updated.
Adapter field values	Specifies values for the adapter fields passed in the HTTP request when an HTML form is submitted. A field value can include new values entered by the end user, the original values of the adapter field, and uploaded files.
Record keys	Specifies keys that uniquely identify each record.

Generating action responses

Action response objects generate an HTTP response on behalf of an adapter action component. The adapter action indicates the type of response by setting properties within the object, or by calling methods in the action response object. The properties include:

- *RedirectOptions*—The redirect options indicate whether to perform an HTTP redirect instead of returning HTML content.
- *ExecutionStatus*—Setting the status to success causes the default action response to be the content of the success page identified in the Action Request.

The action response methods include:

- *RespondWithPage*—The adapter action calls this method when a particular Web page module should generate the response.
- *RespondWithComponent*—The adapter action calls this method when the response should come from the Web page module containing this component.
- *RespondWithURL*—The adapter action calls this method when the response is a redirect to a specified URL.

When responding with a page, the action response object attempts to use the page dispatcher to generate page content. If it does not find the page dispatcher, it calls the Web page module directly.

The following figure illustrates how action request and action response objects handle a request.

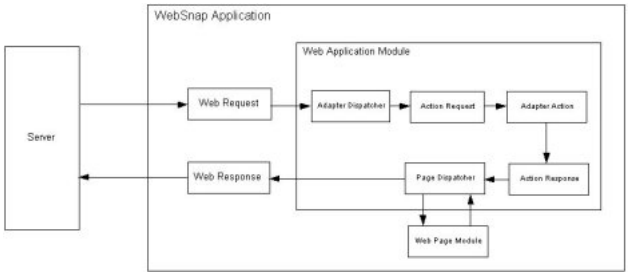

Image request

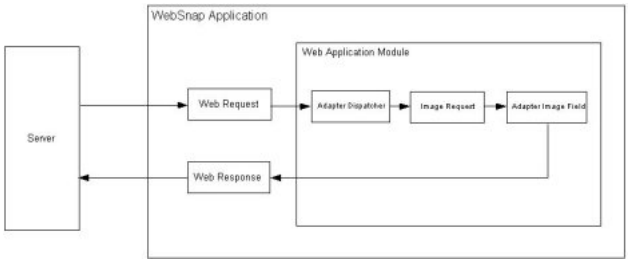

The image request object is responsible for breaking the HTTP request down into the information required by the adapter image field to generate an image. The types of information represented by the Image Request include:

- Component name - Identifies the adapter field component.
- Image request parameters - Identifies the parameters needed by the adapter image. For example, the *TDataSetAdapterImageField* object needs key values to identify the record that contains the image.

Image response

The image response object contains the *TWebResponse* object. Adapter fields respond to an adapter request by writing an image to the Web response object.

The following figure illustrates how adapter image fields respond to a request.

Types of Web Server Applications (see page 2249)

The Structure of a Web Broker Application (see page 2286)

3.2.5.5.3.2 Dispatcher Components

The dispatcher components in the Web application module control the flow of the application. The dispatchers determine how to handle certain types of HTTP request messages by examining the HTTP request.

The adapter dispatcher component (*TAdapterDispatcher*) looks for a content field, or a query field, that identifies an adapter action component or an adapter image field component. If the adapter dispatcher finds a component, it passes control to that component.

The Web dispatcher component (*TWebDispatcher*) maintains a collection of action items (of type *TWebActionItem*) that know how to handle certain types of HTTP request messages. The Web dispatcher looks for an action item that matches the request. If it finds one, it passes control to that action item. The Web dispatcher also looks for auto-dispatching components that can handle the request.

The page dispatcher component (*TPageDispatcher*) examines the *PathInfo* property of the *TWebRequest* object, looking for the

name of a registered Web page module. If the dispatcher finds a Web page module name, it passes control to that module.

See Also

Types of Web Server Applications (see page 2249)

The Structure of a Web Broker Application (see page 2286)

3.2.5.5.3.3 Dispatching Action Items

When responding to a request, the Web dispatcher (*TWebDispatcher*) searches through its list of action items for one that:

- matches the PathInfo portion of the target URL's request message, and
- can provide the service specified as the method of the request message.

It accomplishes this by comparing the *PathInfo* and *MethodType* properties of the *TWebRequest* object with the properties of the same name on the action item.

When the dispatcher finds the appropriate action item, it causes that action item to fire. When the action item fires, it does one of the following:

- Fills in the response content and sends the response, or signals that the request has been completely handled.
- Adds to the response, and then allows other action items to complete the job.
- Defers the request to other action items.

After the dispatcher has checked all of its action items, if the message was not handled correctly, the dispatcher checks for specially registered auto-dispatching components that do not use action items. (These components are specific to multi-tiered database applications.) If the request message is still not fully handled, the dispatcher calls the default action item. The default action item does not need to match either the target URL or the method of the request.

Types of Web Server Applications (see page 2249)

The Structure of a Web Broker Application (see page 2286)

3.2.5.5.3.4 Dispatching Requests and Responses

One reason to use WebSnap for your Web server application development is that WebSnap components automatically handle HTML requests and responses. Instead of writing event handlers for common page transfer chores, you can focus your efforts on your business logic and server design. Still, it can be helpful to understand how WebSnap applications handle HTML requests and responses. This section gives you an overview of that process.

Before handling any requests, the Web application module initializes the Web context object (of type TWebContext). The Web context object, which is accessed by calling the global WebContext function, provides global access to variables used by components servicing the request. For example, the Web context contains the TWebRequest and TWebResponse objects to represent the HTTP request message and the response that should be returned.

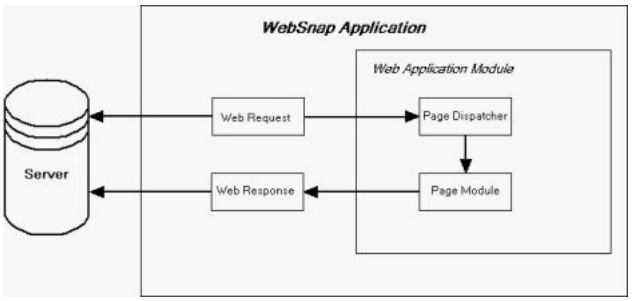
The following topics describe Web request handling:

- Using dispatcher components (see page 2319)
- Adapter dispatcher operation (see page 2317)
- Dispatching action items (see page 2320)
- Page dispatcher operation (see page 2321)

See Also

Types of Web Server Applications (see page 2249)

The Structure of a Web Broker Application (see page 2286)



3.2.5.5.3.5 Page dispatcher operation

When the page dispatcher receives a client request, it determines the page name by checking the PathInfo portion of the target URL's request message. If the PathInfo portion is not blank, the page dispatcher uses the ending word of PathInfo as the page name. If the PathInfo portion is blank, the page dispatcher tries to determine a default page name.

If the page dispatcher's *DefaultPage* property contains a page name, the page dispatcher uses this name as the default page name. If the *DefaultPage* property is blank and the Web application module is a page module, the page dispatcher uses the name of the Web application module as the default page name.

If the page name is not blank, the page dispatcher searches for a Web page module with a matching name. If it finds a Web page module, it calls that module to generate a response. If the page name is blank, or if the page dispatcher does not find a Web page module, the page dispatcher raises an exception.

The following figure shows how the page dispatcher responds to a request.

3.2.5.5.4 Fundamental WebSnap components

Topics

Name	Description
Web modules (see page 2322)	
Adapters (see page 2325)	Adapters define a script interface to your server application. They allow you to insert scripting languages into a page and retrieve information by making calls from your script code to the adapters. For example, you can use an adapter to define data fields to be displayed on an HTML page. A scripted HTML page can then contain HTML content and script statements that retrieve the values of those data fields. This is similar to the transparent tags used in Web Broker applications. Adapters also support actions that execute commands. For example, clicking on a hyperlink or submitting an HTML form... more (see page 2325)

Fundamental WebSnap Components (see page 2326)	Before you can build Web server applications using WebSnap, you must first understand the fundamental components used in WebSnap development. They fall into three categories: • Web modules (see page 2324), which contain the components that make up the application and define pages • Adapters (see page 2325), which provide an interface between HTML pages and the Web server application itself • Page producers (see page 2326), which contain the routines that create the HTML pages to be served to the end user The following sections examine each type of component in more detail.
Page Producers (see page 2326)	Page producers to generate content on behalf of a Web page module. Page producers provide the following functionality: • They generate HTML content. • They can reference an external file using the HTMLFile property, or the internal string using the HTMLDoc property. • When the producers are used with a Web page module, the template can be a file associated with a unit. • Producers dynamically generate HTML that can be inserted into the template using transparent tags or active scripting. Transparent tags can be used in the same way as WebBroker applications. To learn more about using transparent tags, see Converting HTML-transparent (see page 2269)... more (see page 2326)

3.2.5.5.4.1 Web modules

Topics

Name	Description
Web Application Module Types (see page 2323)	Web application modules provide centralized control for business rules and non-visual components in the Web application. The two types of Web application modules are tabulated below. ***Web application module types***
Web Data Modules (see page 2324)	Like standard data modules, Web data modules are a container for components from the palette. Data modules provide a design surface for adding, removing, and selecting components. The Web data module differs from a standard data module in the structure of the unit and the interfaces that the Web data module implements. Use the Web data module as a container for components that are shared across your application. For example, you can put a dataset component in a data module and access the dataset from both: • a page module that displays a grid, and • a page module that displays an... more (see page 2324)

Web Modules (see page 2324)	Web modules are the basic building block of WebSnap applications. Every WebSnap server application must have at least one Web module. More can be added as needed. There are four Web module types: • Web application page modules (TWebAppPageModule objects) • *Web application data modules* (TWebAppDataModule objects) • *Web page modules (*TWebPageModule objects) • *Web data modules (*TWebDataModule objects) Web page modules and Web application page modules provide content for Web pages. Web data modules and Web application data modules act as containers for components shared across your application; they serve the same purpose in WebSnap applications that ordinary data modules serve... more (see page 2324)
Web Page Modules (see page 2325)	Each Web page module has a page producer associated with it. When a request is received, the page dispatcher analyzes the request and calls the appropriate page module to process the request and return the content of the page. Like Web data modules, Web page modules are containers for components. A Web page module is more than a mere container, however. A Web page module is used specifically to produce a Web page.

3.2.5.5.4.1.1 Web Application Module Types

Web application modules provide centralized control for business rules and non-visual components in the Web application. The two types of Web application modules are tabulated below.

Web application module types

Web application module type	Description
Page	Creates a content page. The page module contains a page producer which is responsible for generating the content of a page. The page producer displays its associated page when the HTTP request pathinfo matches the page name. The page can act as the default page when the pathinfo is blank.
Data	Used as a container for components shared by other modules, such as database components used by multiple Web page modules.

Web application modules act as containers for components that perform functions for the application as a whole—such as dispatching requests, managing sessions, and maintaining user lists. If you are already familiar with the Web Broker architecture, you can think of Web application modules as being similar to *TWebApplication* objects. Web application modules also contain the functionality of a regular Web module, either page or data, depending on the Web application module type. Your project can contain only one Web application module. You will never need more than one anyway; you can add regular Web modules to your server to provide whatever extra features you want.

Use the Web application module to contain the most basic features of your server application. If your server will maintain a home page of some sort, you may want to make your Web application module a *TWebAppPageModule* instead of a *TWebAppDataModule*, so you don't have to create an extra Web page module for that page.

Types of Web Server Applications (see page 2249)

The Structure of a Web Broker Application (see page 2286)

3.2.5.5.4.1.2 Web Data Modules

Like standard data modules, Web data modules are a container for components from the palette. Data modules provide a design surface for adding, removing, and selecting components. The Web data module differs from a standard data module in the structure of the unit and the interfaces that the Web data module implements.

Use the Web data module as a container for components that are shared across your application. For example, you can put a dataset component in a data module and access the dataset from both:

- a page module that displays a grid, and
- a page module that displays an input form.

You can also use Web data modules to contain sets of components that can be used by several different Web server applications.

Structure of a Web data module unit

Standard data modules have a variable called a form variable, which is used to access the data module object. Web data modules replace the variable with a function, which is defined in a Web data module's unit and has the same name as the Web data module. The function's purpose is the same as that of the variable it replaces. WebSnap applications may be multi-threaded and may have multiple instances of a particular module to service multiple requests concurrently. Therefore, the function is used to return the correct instance.

The Web data module unit also registers a factory to specify how the module should be managed by the WebSnap application. For example, flags indicate whether to cache the module and reuse it for other requests or to destroy the module after a request has been serviced.

The Web Application Object (see page 2288)

Using Data Modules and Remote Data Modules (see page 1912)

Web Modules (see page 2324)

3.2.5.5.4.1.3 Web Modules

Web modules are the basic building block of WebSnap applications. Every WebSnap server application must have at least one Web module. More can be added as needed. There are four Web module types:

- Web application page modules (TWebAppPageModule objects)
- *Web application data modules* (TWebAppDataModule objects)
- *Web page modules (*TWebPageModule objects)
- *Web data modules (*TWebDataModule objects)

Web page modules and Web application page modules provide content for Web pages. Web data modules and Web application data modules act as containers for components shared across your application; they serve the same purpose in WebSnap applications that ordinary data modules serve in regular applications. You can include any number of Web page or data modules in your server application.

You may be wondering how many Web modules your application needs. Every WebSnap application needs one (and only one) Web application module of some type. Beyond that, you can add as many Web page or data modules as you need.

For Web page modules, a good rule of thumb is one per page style. If you intend to implement a page that can use the format of an existing page, you may not need a new Web page module. Modifications to an existing page module may suffice. If the page is very different from your existing modules, you will probably want to create a new module. For example, let's say you are trying to build a server to handle online catalog sales. Pages which describe available products might all share the same Web page module, since the pages can all contain the same basic information types using the same layout. An order form, however, would probably require a different Web page module, since the format and function of an order form is different from that of an item description page.

The rules are different for Web data modules. Components that can be shared by many different Web modules should be placed in a Web data module to simplify shared access. You will also want to place components that can be used by many different Web applications in their own Web data module. That way you can easily share those items among applications. Of course, if neither of these circumstances applies you might choose not to use Web data modules at all. Use them the same way you would use regular data modules, and let your own judgment and experience be your guide.

The following topics describe Web modules in greater detail:

- Web application module types (see page 2323)
- Web page modules (see page 2325)
- Web data modules (see page 2324)

See Also

The Web Application Object (see page 2288)

Using Data Modules and Remote Data Modules (see page 1912)

3.2.5.5.4.1.4 Web Page Modules

Each Web page module has a page producer associated with it. When a request is received, the page dispatcher analyzes the request and calls the appropriate page module to process the request and return the content of the page.

Like Web data modules, Web page modules are containers for components. A Web page module is more than a mere container, however. A Web page module is used specifically to produce a Web page.

Page producer component

Web page modules have a property that identifies the page producer (see page 2326) component responsible for generating content for the page. The WebSnap page module wizard automatically adds a producer when creating a Web page module. You can change the page producer component later by dropping in a different producer from the WebSnap category . However, if the page module has a template file, be sure that the content of this file is compatible with the replacement producer component.

Page name

Web page modules have a page name that can be used to reference the page in an HTTP request or within the application's logic. A factory in the Web page module's unit specifies the page name for the Web page module.

Producer template

Most page producers use a template. HTML templates typically contain some static HTML mixed in with transparent tags or server-side scripting. When page producers create their content, they replace the transparent tags with appropriate values and execute the server-side script to produce the HTML that is displayed by a client browser. (The XSLPageProducer is an exception to this. It uses XSL templates, which contain XSL rather than HTML. The XSL templates do not support transparent tags or server-side script.)

Web page modules may have an associated template file that is managed as part of the unit. A managed template file appears in the **Project Manager** and has the same base file name and location as the unit service file. If the Web page module does not have an associated template file, the properties of the page producer component specify the template.

See Also

The Web Application Object (see page 2288)

Web Modules (see page 2324)

3.2.5.5.4.2 Adapters

Adapters define a script interface to your server application. They allow you to insert scripting languages into a page and retrieve information by making calls from your script code to the adapters. For example, you can use an adapter to define data fields to be displayed on an HTML page. A scripted HTML page can then contain HTML content and script statements that retrieve the

values of those data fields. This is similar to the transparent tags used in Web Broker applications. Adapters also support actions that execute commands. For example, clicking on a hyperlink or submitting an HTML form can initiate adapter actions.

Adapters simplify the task of creating HTML pages dynamically. By using adapters in your application, you can include object-oriented script that supports conditional logic and looping. Without adapters and server-side scripting, you must write more of your HTML generation logic in event handlers. Using adapters can significantly reduce development time.

See Server-side scripting in WebSnap (see page 2333) for more details about scripting.

Four types of adapter components can be used to create page content: fields, actions, errors and records.

Fields

Fields are components that the page producer uses to retrieve data from your application and to display the content on a Web page. Fields can also be used to retrieve an image. In this case, the field returns the address of the image written to the Web page. When a page displays its content, a request is sent to the Web server application, which invokes the adapter dispatcher to retrieve the actual image from the field component.

Actions

Actions are components that execute commands on behalf of the adapter. When a page producer generates its page, the scripting language calls adapter action components to return the name of the action along with any parameters necessary to execute the command. For example, consider clicking a button on an HTML form to delete a row from a table. This returns, in the HTTP request, the action name associated with the button and a parameter indicating the row number. The adapter dispatcher locates the named action component and passes the row number as a parameter to the action.

Errors

Adapters keep a list of errors that occur while executing an action. Page producers can access this list of errors and display them in the Web page that the application returns to the end user.

Records

Some adapter components, such as *TDataSetAdapter*, represent multiple records. The adapter provides a scripting interface which allows iteration through the records. Some adapters support paging and iterate only through the records on the current page.

Types of Web Server Applications (see page 2249)

The Structure of a Web Broker Application (see page 2286)

3.2.5.5.4.3 Fundamental WebSnap Components

Before you can build Web server applications using WebSnap, you must first understand the fundamental components used in WebSnap development. They fall into three categories:

- Web modules (see page 2324), which contain the components that make up the application and define pages
- Adapters (see page 2325), which provide an interface between HTML pages and the Web server application itself
- Page producers (see page 2326), which contain the routines that create the HTML pages to be served to the end user

The following sections examine each type of component in more detail.

See Also

The Web Application Object (see page 2288)

3.2.5.5.4.4 Page Producers

Page producers to generate content on behalf of a Web page module. Page producers provide the following functionality:

- They generate HTML content.
- They can reference an external file using the HTMLFile property, or the internal string using the HTMLDoc property.
- When the producers are used with a Web page module, the template can be a file associated with a unit.
- Producers dynamically generate HTML that can be inserted into the template using transparent tags or active scripting. Transparent tags can be used in the same way as WebBroker applications. To learn more about using transparent tags, see Converting HTML-transparent tags (see page 2269). Active scripting support allows you to embed JScript or VBScript inside the HTML page.

The standard WebSnap method for using page producers is as follows. When you create a Web page module, you must choose a page producer type in the Web Page Module wizard. You have many choices, but most WebSnap developers prototype their pages by using an adapter page producer, TAdapterPageProducer. The adapter page producer lets you build a prototype Web page using a process analogous to the standard component model. You add a type of form, an adapter form, to the adapter page producer. As you need them, you can add adapter components (such as adapter grids) to the adapter form. Using adapter page producers, you can create Web pages in a way that is similar to the standard technique for building user interfaces.

There are some circumstances where switching from an adapter page producer to a regular page producer is more appropriate. For example, part of the function of an adapter page producer is to dynamically generate script in a page template at runtime. You may decide that static script would help optimize your server. Also, users who are experienced with script may want to make changes to the script directly. In this case, a regular page producer must be used to avoid conflicts between dynamic and static script. To learn how to change to a regular page producer, see the Advanced HTML design (see page 2311) topic.

You can also use page producers the same way you would use them in Web Broker applications, by associating the producer with a Web dispatcher action item. The advantages of using the Web page module are

- the ability to preview the page's layout without running the application, and
- the ability to associate a page name with the module, so that the page dispatcher can call the page producer automatically.

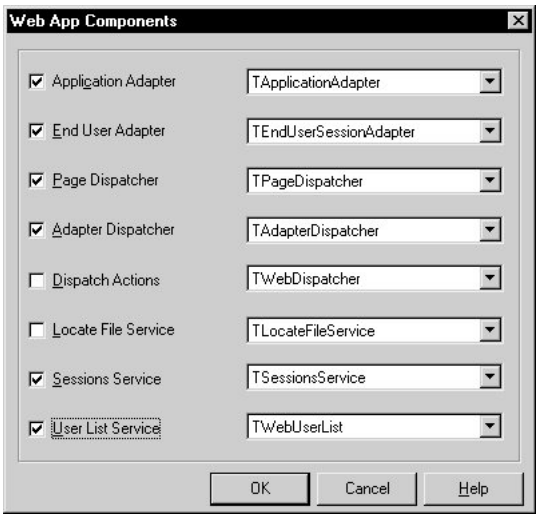
Creating Web Server Applications with WebSnap (see page 2249)

The Structure of a Web Broker Application (see page 2286)

3.2.5.5.5 Login support

Topics

Name	Description
Adding Login Support (see page 2328)	In order to implement login support, you need to make sure your Web application module has the following components: • A user list service (an object of type TWebUserList), which contains the usernames, passwords and permissions for server users • A sessions service (TSessionsService), which stores information about users currently logged in to the server • An end user adapter (TEndUserSessionAdapter) which handles actions associated with logging in When you first create your Web server application, you can add these components using the New WebSnap Application dialog box. Click the Components button on that dialog to display the New Web App Components dialog... more (see page 2328)



Login Pages (see page 2329)	Of course, your Websnap application also needs a login page. Users enter their username and password for authentication, either while trying to access a restricted page or prior to such an attempt. The user can also specify which page they receive when authentication is completed. If the username and password match a user in the Web user list, the user acquires the appropriate access rights and is forwarded to the page specified on the login page. If the user isn't authenticated, the login page may be redisplayed (the default action) or some other action may occur. Fortunately, WebSnap makes it... more (see page 2329)
Login Support (see page 2330)	Many Web server applications require login support. For example, a server application may require a user to login before granting access to some parts of a Web site. Pages may have a different appearance for different users; logins may be necessary to enable the Web server to send the right pages. Also, because servers have physical limitations on memory and processor cycles, server applications sometimes need the ability to limit the number of users at any given time. With WebSnap, incorporating login support into your Web server application is fairly simple and straightforward. You can add login support, either by... more (see page 2330)
Setting Pages to Require Logins (see page 2330)	Once you have a working login page, you must require logins for those pages which need controlled access. The easiest way to have a page require logins is to design that requirement into the page. When you first create a Web page module, check the Login Required box in the Page section of the New WebSnap Page Module dialog box. If you create a page without requiring logins, you can change your mind later.
User Access Rights (see page 2331)	User access rights are an important part of any Web server application. You need to be able to control who can view and modify the information your server provides. For example, let's say you are building a server application to handle online retail sales. It makes sense to allow users to view items in your catalog, but you don't want them to be able to change your prices! Clearly, access rights are an important issue. Fortunately, WebSnap offers you several ways to control access to pages and server content. In previous topics, you saw how you can control page access... more (see page 2331)
Using the Sessions Service (see page 2332)	The sessions service, which is an object of type TSessionsService, keeps track of the users who are logged into your Web server application. The sessions service is responsible for assigning a different session for each user and for associating name/value pairs (such as a username) with a user. Information contained in a sessions service is stored in the application's memory. Therefore, the Web server application must keep running between requests for the sessions service to work. Some server application types, such as CGI, terminate between requests. **Note:** If you want your application to support logins, be sure to use a... more (see page 2332)

3.2.5.5.5.1 Adding Login Support

In order to implement login support, you need to make sure your Web application module has the following components:

- A user list service (an object of type TWebUserList), which contains the usernames, passwords and permissions for server users
- A sessions service (TSessionsService), which stores information about users currently logged in to the server
- An end user adapter (TEndUserSessionAdapter) which handles actions associated with logging in

When you first create your Web server application, you can add these components using the New WebSnap Application dialog box. Click the Components button on that dialog to display the New Web App Components dialog box. Check the End User Adapter, Sessions Service and Web User List boxes. Select *TEndUserSessionAdapter* on the drop down menu next to the End User Adapter box to select the end user adapter type. (The default choice, TEndUserSessionAdapter, is not appropriate for login support because it cannot track the current user.) When you're finished, your dialog should look like the one shown below. Click OK twice to dismiss the dialog boxes. Your Web application module now has the necessary components for login support.

If you are adding login support to an existing Web application module, you can drag these components directly into your module from the WebSnap category of the **Tool Palette**. The Web application module will configure itself automatically.

The sessions service and the end user adapter may not require your attention during your design phase, but the Web user list probably will. You can add default users and set their read/modify permissions through the WebUserList component editor. Double-click on the component to display an editor which lets you set usernames, passwords and access rights. For more information on how to set up access rights, see the topic "User access rights" (see page 2331).

For information on login support, see Login Support (see page 2330).

3.2.5.5.5.2 Login Pages

Of course, your Websnap application also needs a login page. Users enter their username and password for authentication, either while trying to access a restricted page or prior to such an attempt. The user can also specify which page they receive when authentication is completed. If the username and password match a user in the Web user list, the user acquires the appropriate access rights and is forwarded to the page specified on the login page. If the user isn't authenticated, the login page may be redisplayed (the default action) or some other action may occur.

Fortunately, WebSnap makes it easy to create a simple login page using a Web page module and the adapter page producer. To create a login page, start by creating a new Web page module. Choose **File ▸ New ▸ Other,** and select WebSnap from the Delphi Projects folder. In the right pane of the New Items window select the WebSnap Page Module. Select AdapterPageProducer as the page producer type. Fill in the other options however you like. Login tends to be a good name for the login page.

Now you should add the most basic login page fields: a username field, a password field, a selection box for selecting which page the user receives after logging in, and a Login button which submits the page and authenticates the user.

To add these fields:

1. Add a TLoginFormAdapter component (which you can find on the WebSnap category of the **Tool Palette**) to the Web page module you just created.
2. Double-click the *AdapterPageProducer* component to display a Web page editor window.
3. Right-click the *AdapterPageProducer* in the top left pane and select New Component. In the Add Web Component dialog box, select *AdapterForm* and click OK.
4. Add an *AdapterFieldGroup* to the AdapterForm. (Right-click the *AdapterForm* in the top left pane and select New Component. In the Add Web Component dialog box, select *AdapterFieldGroup* and click OK.)
5. Now go to the **Object Inspector** and set the *Adapter* property of your *AdapterFieldGroup* to your *LoginFormAdapter*. The UserName, Password and NextPage fields should appear automatically in the Browser tab of the Web page editor (accessed by double clicking the *AdapterPageProducer*) .

So, WebSnap takes care of most of the work in a few simple steps. The login page is still missing a Login button, which submits the information on the form for authentication.

To add a Login button:

1. Add an *AdapterCommandGroup* to the *AdapterForm*.
2. Add an *AdapterActionButton* to the *AdapterCommandGroup*. Change its *DisplayComponent* to AdapterFieldGroup using the **Object Inspector**.
3. Click on the *AdapterActionButton* (listed in the upper right pane of the Web page editor) and change its *ActionName* property to Login using the **Object Inspector**. You can see a preview of your login page in the Web page editor's Browser tab.

If the button doesn't appear below the *AdapterFieldGroup*, make sure that the *AdapterCommandGroup* is listed below the *AdapterFieldGroup* on the Web page editor. If it appears above, select the *AdapterCommandGroup* and click the down arrow on the Web page editor. (In general, Web page elements appear vertically in the same order as they appear in the Web page editor.)

There is one more step necessary before your login page becomes functional. You need to specify which of your pages is the login page in your end user session adapter. To do so, select the *EndUserSessionAdapter* component in your Web application module. In the **Object Inspector**, change the *LoginPage* property to the name of your login page. Your login page is now enabled for all the pages in your Web server application.

3.2.5.5.5.3 Login Support

Many Web server applications require login support. For example, a server application may require a user to login before granting access to some parts of a Web site. Pages may have a different appearance for different users; logins may be necessary to enable the Web server to send the right pages. Also, because servers have physical limitations on memory and processor cycles, server applications sometimes need the ability to limit the number of users at any given time.

With WebSnap, incorporating login support into your Web server application is fairly simple and straightforward. You can add login support, either by designing it in from the beginning of your development process or by retrofitting it onto an existing application.

For additional information on adding login support, refer to Adding Login Support (see page 2328).

3.2.5.5.5.4 Setting Pages to Require Logins

Once you have a working login page, you must require logins for those pages which need controlled access. The easiest way to have a page require logins is to design that requirement into the page. When you first create a Web page module, check the Login Required box in the Page section of the New WebSnap Page Module dialog box.

If you create a page without requiring logins, you can change your mind later.

To require logins after a Web page module has been created:

1. Open the source code file associated with the Web page module in the editor.
2. Scroll down to the implementation section. In the parameters for the WebRequestHandler.AddWebModuleFactory command, find the creator of the TWebPageInfo object. It should look like this:

```
TWebPageInfo.Create([wpPublished {, wpLoginRequired}], '.html')
```

3. Uncomment the *wpLoginRequired* portion of the parameter list by removing the curly braces. The TWebPageInfo creator should now look like this:

```
TWebPageInfo.Create([wpPublished , wpLoginRequired], '.html')
static TWebPageInit WebInit(__classid(TAdapterPageProducerPage3), crOnDemand, caCache,
PageAccess << wpPublished << wpLoginRequired, ".html", "", "", "", "");
```

To remove the login requirement from a page, reverse the process and recomment the *wpLoginRequired* portion of the creator.

Note: You can use the same process to make the page published or not. Simply add or remove comment marks around the *wpPublished* portion as needed.

3.2.5.5.5.5 User Access Rights

User access rights are an important part of any Web server application. You need to be able to control who can view and modify the information your server provides. For example, let's say you are building a server application to handle online retail sales. It makes sense to allow users to view items in your catalog, but you don't want them to be able to change your prices! Clearly, access rights are an important issue.

Fortunately, WebSnap offers you several ways to control access to pages and server content. In previous topics, you saw how you can control page access by requiring logins. You have other options as well. For example:

- You can show data fields in an edit box to users with appropriate modify access rights; other users will see the field contents, but not have the ability to edit them.
- You can hide specific fields from users who don't have the correct view access rights.
- You can prevent unauthorized users from receiving specific pages.

Descriptions for implementing these behaviors are included in this topic.

Dynamically displaying fields as edit or text boxes

If you use the adapter page producer, you can change the appearance of page elements for users with different access rights. For example, the Biolife demo (found in the WebSnap subdirectory of the Demos directory) contains a form page which shows all the information for a given species. The form appears when the user clicks a Details button on the grid. A user logged in as Will sees data displayed as plain text. Will is not allowed to modify the data, so the form doesn't give him a mechanism to do so. User Ellen does have modify permissions, so when Ellen views the form page, she sees a series of edit boxes which allow her to change field contents. Using access rights in this manner can save you from creating extra pages.

The appearance of some page elements, such as *TAdapterDisplayField*, is determined by its *ViewMode* property. If *ViewMode* is set to *vmToggleOnAccess*, the page element will appear as an edit box to users with modify access. Users without modify access will see plain text. Set the *ViewMode* property to *vmToggleOnAccess* to allow the page element's appearance and function to be determined dynamically.

A Web user list is a list of *TWebUserListItem* objects, one for each user who can login to the system. Permissions for users are stored in their Web user list item's *AccessRights* property. *AccessRights* is a text string, so you are free to specify permissions any way you like. Create a name for every kind of access right you want in your server application. If you want a user to have multiple access rights, separate items in the list with a space, semicolon or comma.

Access rights for fields are controlled by their *ViewAccess* and *ModifyAccess* properties. *ViewAccess* stores the name of the access rights needed to view a given field. *ModifyAccess* dictates what access rights are needed to modify field data. These properties appear in two places: in each field and in the adapter object that contains them.

Checking access rights is a two-step process. When deciding the appearance of a field in a page, the application first checks the field's own access rights. If the value is an empty string, the application then checks the access rights for the adapter which contains the field. If the adapter property is empty as well, the application will follow its default behavior. For modify access, the default behavior is to allow modifications by any user in the Web user list who has a non-empty *AccessRights* property. For view access, permission is automatically granted when no view access rights are specified.

Hiding fields and their contents

You can hide the contents of a field from users who don't have appropriate view permissions. First set the *ViewAccess* property for the field to match the permission you want users to have. Next, make sure that the *ViewAccess* for the field's page element is set to *vmToggleOnAccess*. The field caption will appear, but the value of the field won't.

Of course, it is often best to hide all references to the field when a user doesn't have view permissions. To do so, set the *HideOptions* for the field's page element to include *hoHideOnNoDisplayAccess*. Neither the caption nor the contents of the field will be displayed.

Preventing page access

You may decide that certain pages should not be accessible to unauthorized users. To grant check access rights before displaying pages, alter your call to the *TWebPageInfo* constructor in the Web request handler's AddWebModuleFactory command. This command appears in the initialization section of the source code for your module.

The constructor for TWebPageInfo takes up to 6 arguments. WebSnap usually leaves four of them set to default values (empty strings), so the call generally looks like this:

```
TWebPageInfo.Create([wpPublished, wpLoginRequired], '.html')
static TWebPageInit WebInit(__classid(TAdapterPageProducerPage3), crOnDemand, caCache,
PageAccess << wpPublished /* << wpLoginRequired */, ".html", "", "", "", "");
```

To check permissions before granting access, you need to supply the string for the necessary permission in the sixth parameter. For example, let's say that the permission is called "Access". This is how you could modify the creator:

```
TWebPageInfo.Create([wpPublished, wpLoginRequired], '.html', '', '', '', 'Access')
static TWebPageInit WebInit(__classid(TAdapterPageProducerPage3), crOnDemand, caCache,
PageAccess << wpPublished /* << wpLoginRequired */, ".html", "", "", "", "Access");
```

Access to the page will now be denied to anyone who lacks Access permission.

3.2.5.5.5.6 Using the Sessions Service

The sessions service, which is an object of type TSessionsService, keeps track of the users who are logged into your Web server application. The sessions service is responsible for assigning a different session for each user and for associating name/value pairs (such as a username) with a user.

Information contained in a sessions service is stored in the application's memory. Therefore, the Web server application must keep running between requests for the sessions service to work. Some server application types, such as CGI, terminate between requests.

Note: If you want your application to support logins, be sure to use a server type that does not terminate between requests. If your project produces a Web App debugger executable, you must have the application running in the background before it receives a page request. Otherwise it will terminate after each page request, and users will never be able to get past the login page.

There are two important properties in the sessions service which you can use to change default server behavior. The *MaxSessions* property specifies how many users can be logged into the system at any given time. The default value for *MaxSessions* is -1, which places no software limitation on the number of allowed users. Of course, your server hardware can still run short of memory or processor cycles for new users, which can adversely affect system performance. If you are concerned that excessive numbers of users might overwhelm your server, be sure to set *MaxSessions* to an appropriate value.

The *DefaultTimeout* property specifies the defaut time-out period in minutes. After *DefaultTimeout* minutes have passed without any user activity, the session is automatically terminated. If the user had logged in, all login information is lost.. The default value is 20. You can override the default value in any given session by changing its *TimeoutMinutes* property.

3.2.5.5.6 Server-side scripting in WebSnap

Topics

Name	Description
Script Objects (see page 2333)	Script objects are objects that script commands can reference. You make objects available for scripting by registering an *IDispatch* interface to the object with the active scripting engine. The following objects are available for scripting: ***Script objects***

Server-side Scripting in WebSnap (see page 2333)	Page producer templates can include scripting languages such as JScript or VBScript. The page producer executes the script in response to a request for the producer's content. Because the Web server application evaluates the script, it is called server-side script, as opposed to client-side script (which is evaluated by the browser). This topic provides a conceptual overview of server-side scripting and how it is used by WebSnap applications. Although server-side scripting is a valuable part of WebSnap, it is not essential that you use scripting in your WebSnap applications. Scripting is used for HTML generation and nothing else. It allows... more (see page 2333)

3.2.5.5.6.1 Script Objects

Script objects are objects that script commands can reference. You make objects available for scripting by registering an *IDispatch* interface to the object with the active scripting engine. The following objects are available for scripting:

Script objects

Script object	Description
Application	Provides access to the application adapter of the Web Application module.
EndUser	Provides access to the end user adapter of the Web Application module.
Session	Provides access to the session object of the Web Application module.
Pages	Provides access to the application pages.
Modules	Provides access to the application modules.
Page	Provides access to the current page
Producer	Provides access to the page producer of the Web Page module.
Response	Provides access to the WebResponse. Use this object when tag replacement is not desired.
Request	Provides access to the WebRequest.
Adapter objects	All of the adapter components on the current page can be referenced without qualification. Adapters in other modules must be qualified using the Modules objects.

Script objects on the current page, which all use the same adapter, can be referenced without qualification. Script objects on other pages are part of another page module and have a different adapter object. They can be accessed by starting the script object reference with the name of the adapter object. For example,

```
<%= FirstName %>
```

displays the contents of the *FirstName* property of the current page's adapter. The following script line displays the *FirstName* property of Adapter1, which is in another page module:

```
<%= Adapter1.FirstName %>
```

3.2.5.5.6.2 Server-side Scripting in WebSnap

Page producer templates can include scripting languages such as JScript or VBScript. The page producer executes the script in response to a request for the producer's content. Because the Web server application evaluates the script, it is called server-side script, as opposed to client-side script (which is evaluated by the browser).

This topic provides a conceptual overview of server-side scripting and how it is used by WebSnap applications. Although server-side scripting is a valuable part of WebSnap, it is not essential that you use scripting in your WebSnap applications.

Scripting is used for HTML generation and nothing else. It allows you to insert application data into an HTML page. In fact, almost all of the properties exposed by adapters and other script-enabled objects are read-only. Server-side script isn't used to change application data, which is still managed by components and event handlers written in your application's source code.

There are other ways to insert application data into an HTML page. You can use Web Broker's transparent tags or some other tag-based solution, if you prefer. For example, several projects in the WebSnap examples directory use XML and XSL instead of scripting. Without scripting, however, you will be forced to write most of your HTML generation logic in source code, which will increase your development time.

The scripting used in WebSnap is object-oriented and supports conditional logic and looping, which can greatly simplify your page generation tasks. For example, your pages may include a data field that can be edited by some users but not others. With scripting, conditional logic can be placed in your template pages which displays an edit box for authorized users and simple text for others. With a tag-based approach, you must program such decision-making into your HTML generating source code.

Active scripting

WebSnap relies on *active scripting* to implement server-side script. Active scripting is a technology created by Microsoft to allow a scripting language to be used with application objects through COM interfaces. Microsoft ships two active scripting languages, VBScript and JScript. Support for other languages is available through third parties.

Script engine

The page producer's *ScriptEngine* property identifies the active scripting engine that evaluates the script within a template. It is set to support JScript by default, but it can also support other scripting languages (such as VBScript).

Note: WebSnap's adapters are designed to produce JScript. You will need to provide your own script generation logic for other scripting languages.

Script blocks

Script blocks, which appear in HTML templates, are delimited by <% and %>. The script engine evaluates any text inside script blocks. The result becomes part of the page producer's content. The page producer writes text outside of a script block after translating any embedded transparent tags. Script blocks can also enclose text, allowing conditional logic and loops to dictate the output of text. For example, the following JScript block generates a list of five numbered lines:

```
<ul>
<% for (i=0;i<5;i++) { %>
   <li>Item <%=i %></li>
<% } %>
</ul>
```

(The <%= delimiter is short for *Response.Write*.)

Creating script

Developers can take advantage of WebSnap features to automatically generate script.

Wizard templates

When creating a new WebSnap application or page module, WebSnap wizards provide a template field that is used to select the initial content for the page module template. For example, the Default template generates JScript which, in turn, displays the application title, page name, and links to published pages.

TAdapterPageProducer

The TAdapterPageProducer builds forms and tables by generating HTML and JScript. The generated JScript calls adapter objects to retrieve field values, field image parameters, and action parameters.

Editing and viewing script

When the Web Page module uses *TAdapterPageProducer* the page module views become available when this component is double-clicked. You can access the page module view with the HTML resulting from the executed script using the HTML Script tab. The HTML Script tab displays the HTML and JScript generated by the *TAdapterPageProducer* object. Consult this view to

see how to write script that builds HTML forms to display adapter fields and execute adapter actions.

Including script in a page

A template can include script from a file or from another page. To include script from a file, use the following code statement:

```
<!-- #include file="filename.html" -->
```

When the template includes script from another page, the script is evaluated by the including page. Use the following code statement to include the unevaluated content of page1.

```
<!-- #include page="page1" -- >
```

Reading and writing over socket connections (see page 2339)	
Responding to socket events (see page 2341)	
Types of socket connections (see page 2344)	
Using socket components (see page 2346)	

3.2.5.6.1 Describing sockets

Topics

Name	Description
Describing Sockets (see page 2336)	Sockets let your network application communicate with other systems over the network. Each socket can be viewed as an endpoint in a network connection. It has an address that specifies: • The system on which it is running. • The types of interfaces it understands. • The port it is using for the connection. A full description of a socket connection includes the addresses of the sockets on both ends of the connection. You can describe the address of each socket endpoint by supplying both the IP address or host (see page 2336) and the port number (see page 2337). Before you can make a socket connection,... more (see page 2336)

Describing the Host (see page 2336)	The host is the system that is running the application that contains the socket. You can describe the host for a socket by giving its IP address, which is a string of four numeric (byte) values in the standard Internet dot notation, such as
Using Ports (see page 2337)	While the IP address provides enough information to find the system on the other end of a socket connection, you also need a port number on that system. Without port numbers, a system could only form a single connection at a time. Port numbers are unique identifiers that enable a single system to host multiple connections simultaneously, by giving each connection a separate port number. One way to look at port numbers is as numeric codes for the services implemented by network applications. This is a convention that allows listening server connections to make themselves available on a fixed port... more (see page 2337)

3.2.5.6.1.1 Describing Sockets

Sockets let your network application communicate with other systems over the network. Each socket can be viewed as an endpoint in a network connection. It has an address that specifies:

- The system on which it is running.
- The types of interfaces it understands.
- The port it is using for the connection.

A full description of a socket connection includes the addresses of the sockets on both ends of the connection. You can describe the address of each socket endpoint by supplying both the IP address or host (see page 2336) and the port number (see page 2337).

Before you can make a socket connection, you must fully describe the sockets that form its endpoints. Some of the information is available from the system your application is running on. For instance, you do not need to describe the local IP address of a client socket—this information is available from the operating system.

The information you must provide depends on the type of socket you are working with. Client sockets must describe the server they want to connect to. Listening server sockets must describe the port that represents the service they provide.

Implementing Services (see page 2338)

Types of Socket Connections (see page 2345)

Using Socket Components (see page 2348)

Responding to Socket Events (see page 2343)

Reading and Writing Over Socket Connections (see page 2341)

3.2.5.6.1.2 Describing the Host

The host is the system that is running the application that contains the socket. You can describe the host for a socket by giving its IP address, which is a string of four numeric (byte) values in the standard Internet dot notation, such as

```
123.197.1.2
```

A single system may support more than one IP address.

IP addresses are often difficult to remember and easy to mistype. An alternative is to use the host name. Host names are aliases for the IP address that you often see in Uniform Resource Locators (URLs). They are strings containing a domain name and service, such as

```
http://www.ASite.com
```

Most Intranets provide host names for the IP addresses of systems on the Internet. You can learn the host name associated with any IP address (if one already exists) by executing the following command from a command prompt:

```
nslookup IPADDRESS
```

where IPADDRESS is the IP address you're interested in. If your local IP address doesn't have a host name and you decide you want one, contact your network administrator. It is common for computers to refer to themselves with the name *localhost* and the IP number 127.0.0.1.

Server sockets do not need to specify a host. The local IP address can be read from the system. If the local system supports more than one IP address, server sockets will listen for client requests on all IP addresses simultaneously. When a server socket accepts a connection, the client socket provides the remote IP address.

Client sockets must specify the remote host by providing either its host name or IP address.

Choosing between a host name and an IP address

Most applications use the host name to specify a system. Host names are easier to remember, and easier to check for typographical errors. Further, servers can change the system or IP address that is associated with a particular host name. Using a host name allows the client socket to find the abstract site represented by the host name, even when it has moved to a new IP address.

If the host name is unknown, the client socket must specify the server system using its IP address. Specifying the server system by giving the IP address is faster. When you provide the host name, the socket must search for the IP address associated with the host name, before it can locate the server system.

See Also

Using Ports (see page 2337)

Parts of a Uniform Resource Locator (see page 2253)

3.2.5.6.1.3 Using Ports

While the IP address provides enough information to find the system on the other end of a socket connection, you also need a port number on that system. Without port numbers, a system could only form a single connection at a time. Port numbers are unique identifiers that enable a single system to host multiple connections simultaneously, by giving each connection a separate port number.

One way to look at port numbers is as numeric codes for the services implemented by network applications. This is a convention that allows listening server connections to make themselves available on a fixed port number so that they can be found by client sockets. Server sockets listen on the port number associated with the service they provide. When they accept a connection to a client socket, they create a separate socket connection that uses a different, arbitrary, port number. This way, the listening connection can continue to listen on the port number associated with the service.

Client sockets use an arbitrary local port number, as there is no need for them to be found by other sockets. They specify the port number of the server socket to which they want to connect so that they can find the server application. Often, this port number is specified indirectly, by naming the desired service.

See Also

Describing the Host (see page 2336)

3.2.5.6.2 Working with Sockets

The socket components let you create an application that can communicate with other systems using TCP/IP and related protocols. Using sockets, you can read and write over connections to other machines without worrying about the details of the underlying networking software. Sockets provide connections based on the TCP/IP protocol, but are sufficiently general to work with related protocols such as User Datagram Protocol (UDP), Xerox Network System (XNS), Digital's DECnet, or Novell's IPX/SPX family.

Using sockets, you can write network servers or client applications that read from and write to other systems. A server or client application is usually dedicated to a single service such as Hypertext Transfer Protocol (HTTP) or File Transfer Protocol (FTP).

Using server sockets, an application that provides one of these services can link to client applications that want to use that service. Client sockets allow an application that uses one of these services to link to server applications that provide the service.

To write applications that use sockets, you should understand

- Implementing services (see page 2338)
- Types of socket connections (see page 2345)
- Describing sockets (see page 2336)
- Using socket components
- Responding to socket events (see page 2343)
- Reading and writing over socket connections (see page 2341)

3.2.5.6.3 Implementing services

Topics

Name	Description
Implementing Services (see page 2338)	Sockets provide one of the pieces you need to write network servers or client applications. For many services, such as HTTP or FTP, third party servers are readily available. Some are even bundled with the operating system, so that there is no need to write one yourself. However, when you want more control over the way the service is implemented, a tighter integration between your application and the network communication, or when no server is available for the particular service you need, then you may want to create your own server or client application. For example, when working with... more (see page 2338)
Services and Ports (see page 2339)	Most standard services are associated, by convention, with specific port numbers. When implementing services, you can consider the port number a numeric code for the service.
Understanding Service Protocols (see page 2339)	Before you can write a network server or client, you must understand the service that your application is providing or using. Many services have standard protocols that your network application must support. If you are writing a network application for a standard service such as HTTP, FTP, or even finger or time, you must first understand the protocols used to communicate with other systems. See the documentation on the particular service you are providing or using. If you are providing a new service for an application that communicates with other systems, the first step is designing the communication protocol for... more (see page 2339)

3.2.5.6.3.1 Implementing Services

Sockets provide one of the pieces you need to write network servers or client applications. For many services, such as HTTP or FTP, third party servers are readily available. Some are even bundled with the operating system, so that there is no need to write one yourself. However, when you want more control over the way the service is implemented, a tighter integration between your application and the network communication, or when no server is available for the particular service you need, then you may want to create your own server or client application. For example, when working with distributed data sets, you may want to write a layer to communicate with databases on other systems.

To implement or use a service using sockets, you must understand

- service protocols (see page 2339)
- services and ports (see page 2339)

3.2.5.6.3.2 Services and Ports

Most standard services are associated, by convention, with specific port numbers. When implementing services, you can consider the port number a numeric code for the service.

See Also

Service Protocols (see page 2339)

Using Ports (see page 2337)

3.2.5.6.3.3 Understanding Service Protocols

Before you can write a network server or client, you must understand the service that your application is providing or using. Many services have standard protocols that your network application must support. If you are writing a network application for a standard service such as HTTP, FTP, or even finger or time, you must first understand the protocols used to communicate with other systems. See the documentation on the particular service you are providing or using.

If you are providing a new service for an application that communicates with other systems, the first step is designing the communication protocol for the servers and clients of this service. What messages are sent? How are these messages coordinated? How is the information encoded?

Communicating with applications

Often, your network server or client application provides a layer between the networking software and an application that uses the service. For example, an HTTP server sits between the Internet and a Web server application that provides content and responds to HTTP request messages.

Sockets provide the interface between your network server or client application and the networking software. You must provide the interface between your application and the clients that use it. You can copy the API of a standard third party server (such as Apache), or you can design and publish your own API.

HTTP Server Activity (see page 2248)

3.2.5.6.4 Reading and writing over socket connections

Topics

Name	Description
Blocking Connections (see page 2340)	When the connection is blocking, your socket must initiate reading or writing over the connection. It cannot wait passively for a notification from the socket connection. Use a blocking socket when your end of the connection is in charge of when reading and writing takes place. For client or server sockets, set the BlockMode property to *bmBlocking* to form a blocking connection. Depending on what else your client application does, you may want to create a new execution thread for reading or writing, so that your application can continue executing code on other threads while it waits for the reading... more (see page 2340)

Non-blocking Connections (see page 2340)	Non-blocking connections read and write asynchronously, so that the transfer of data does not block the execution of other code in you network application. To create a non-blocking connection for client or server sockets, set the BlockMode property to *bmNonBlocking.* When the connection is non-blocking, reading and writing events (see page 2340) inform your socket when the socket on the other end of the connection tries to read or write information.
Reading and Writing Events (see page 2340)	Non-blocking sockets generate reading and writing events when they need to read or write over the connection. You can respond to these notifications in an *OnReceive* or *OnSend* event handler. The socket object associated with the socket connection is provided as a parameter to the read or write event handlers. This socket object provides a number of methods to allow you to read or write over the connection. To read from the socket connection, use the ReceiveBuf or ReceiveIn method. To write to the socket connection, use the SendBuf, SendStream, or SendIn.
Reading and Writing Over Socket Connections (see page 2341)	The reason you form socket connections to other machines is so that you can read or write information over those connections. What information you read or write, or when you read it or write it, depends on the service associated with the socket connection. Reading and writing over sockets can occur asynchronously, so that it does not block the execution of other code in your network application. This is called a non-blocking connection (see page 2340). You can also form blocking connections (see page 2340), where your application waits for the reading or writing to be completed before executing the next line of code.... more (see page 2341)

3.2.5.6.4.1 Blocking Connections

When the connection is blocking, your socket must initiate reading or writing over the connection. It cannot wait passively for a notification from the socket connection. Use a blocking socket when your end of the connection is in charge of when reading and writing takes place.

For client or server sockets, set the BlockMode property to *bmBlocking* to form a blocking connection. Depending on what else your client application does, you may want to create a new execution thread for reading or writing, so that your application can continue executing code on other threads while it waits for the reading or writing over the connection to be completed.

For server sockets, set the *BlockMode* property to *bmBlocking* or *bmThreadBlocking* to form a blocking connection. Because blocking connections hold up the execution of all other code while the socket waits for information to be written or read over the connection, server socket components always spawn a new execution thread for every client connection when the *BlockMode* is *bmThreadBlocking*. When the *BlockMode* is *bmBlocking*, program execution is blocked until a new connection is established.

See Also

Non-blocking Connections (see page 2340)

3.2.5.6.4.2 Non-blocking Connections

Non-blocking connections read and write asynchronously, so that the transfer of data does not block the execution of other code in you network application. To create a non-blocking connection for client or server sockets, set the BlockMode property to *bmNonBlocking.*

When the connection is non-blocking, reading and writing events (see page 2340) inform your socket when the socket on the other end of the connection tries to read or write information.

See Also

Blocking Connections (see page 2340)

Responding to Socket Events (see page 2343)

3.2.5.6.4.3 Reading and Writing Events

Non-blocking sockets generate reading and writing events when they need to read or write over the connection. You can

respond to these notifications in an *OnReceive* or *OnSend* event handler.

The socket object associated with the socket connection is provided as a parameter to the read or write event handlers. This socket object provides a number of methods to allow you to read or write over the connection.

To read from the socket connection, use the ReceiveBuf or ReceiveIn method. To write to the socket connection, use the SendBuf, SendStream, or SendIn.

See Also

Error Events (see page 2342)

Client Events (see page 2342)

Server Events (see page 2343)

Types of Socket Connections (see page 2345)

3.2.5.6.4.4 Reading and Writing Over Socket Connections

The reason you form socket connections to other machines is so that you can read or write information over those connections. What information you read or write, or when you read it or write it, depends on the service associated with the socket connection.

Reading and writing over sockets can occur asynchronously, so that it does not block the execution of other code in your network application. This is called a non-blocking connection (see page 2340). You can also form blocking connections (see page 2340), where your application waits for the reading or writing to be completed before executing the next line of code.

Implementing Services (see page 2338)

Types of Socket Connections (see page 2345)

Describing Sockets (see page 2336)

Using Socket Components (see page 2348)

Responding to Socket Events (see page 2343)

3.2.5.6.5 Responding to socket events

Topics

Name	Description
Client Events (see page 2342)	When a client socket opens a connection, the following events occur: • The socket is set up and initialized for event notification. • An OnCreateHandle event occurs after the server and server socket is created. At this point, the socket object available through the *Handle* property can provide information about the server or client socket that will form the other end of the connection. This is the first chance to obtain the actual port used for the connection, which may differ from the port of the listening sockets that accepted the connection. • The connection request is accepted by the server and completed... more (see page 2342)

Error Events (see page 2342)	Client and server sockets generate OnError events when they receive error messages from the connection. You can write an *OnError* event handler to respond to these error messages. The event handler is passed information about • What socket object received the error notification. • What the socket was trying to do when the error occurred. • The error code that was provided by the error message. You can respond to the error in the event handler, and change the error code to 0 to prevent the socket from raising an exception.
Responding to Socket Events (see page 2343)	When writing applications that use sockets, you can write or read to the socket anywhere in the program. You can write to the socket using the *SendBuf*, *SendStream*, or *Sendln* methods in your program after the socket has been opened. You can read from the socket using the similarly-named methods *ReceiveBuf* and *Receiveln*. The *OnSend* and *OnReceive* events are triggered every time something is written or read from the socket. They can be used for filtering. Every time you read or write, a read or write event is triggered. Both client sockets and server sockets generate error (see page 2342)... more (see page 2343)
Server Events (see page 2343)	Server socket components form two types of connections: listening connections and connections to client applications. The server socket receives events during the formation of each of these connections.

3.2.5.6.5.1 Client Events

When a client socket opens a connection, the following events occur:

- The socket is set up and initialized for event notification.
- An OnCreateHandle event occurs after the server and server socket is created. At this point, the socket object available through the *Handle* property can provide information about the server or client socket that will form the other end of the connection. This is the first chance to obtain the actual port used for the connection, which may differ from the port of the listening sockets that accepted the connection.
- The connection request is accepted by the server and completed by the client socket.
- When the connection is established, the OnConnect notification event occurs.

See Also

Error Events (see page 2342)

Server Events (see page 2343)

Reading and Writing Events (see page 2340)

Using Client Sockets (see page 2348)

Reading and Writing Over Socket Connections (see page 2341)

Using Ports (see page 2337)

3.2.5.6.5.2 Error Events

Client and server sockets generate OnError events when they receive error messages from the connection. You can write an *OnError* event handler to respond to these error messages. The event handler is passed information about

- What socket object received the error notification.
- What the socket was trying to do when the error occurred.
- The error code that was provided by the error message.

You can respond to the error in the event handler, and change the error code to 0 to prevent the socket from raising an exception.

See Also

Client Events (see page 2342)

Server Events (see page 2343)

Reading and Writing Events (see page 2340)

3.2.5.6.5.3 Responding to Socket Events

When writing applications that use sockets, you can write or read to the socket anywhere in the program. You can write to the socket using the *SendBuf*, *SendStream*, or *Sendln* methods in your program after the socket has been opened. You can read from the socket using the similarly-named methods *ReceiveBuf* and *Receiveln*. The *OnSend* and *OnReceive* events are triggered every time something is written or read from the socket. They can be used for filtering. Every time you read or write, a read or write event is triggered.

Both client sockets and server sockets generate error events (see page 2342) when they receive error messages from the connection.

Socket components also receive two events in the course of opening and completing a connection. If your application needs to influence how the opening of the socket proceeds, you must use the *SendBuf* and *ReceiveBuf* methods to respond to these client events (see page 2342) or server events (see page 2343).

Implementing Services (see page 2338)

Types of Socket Connections (see page 2345)

Describing Sockets (see page 2336)

Using Socket Components (see page 2348)

Reading and Writing Over Socket Connections (see page 2341)

3.2.5.6.5.4 Server Events

Server socket components form two types of connections: listening connections and connections to client applications. The server socket receives events during the formation of each of these connections.

Events when listening

Just before the listening connection is formed, the OnListening event occurs. You can use its Handle property to make changes to the socket before it is opened for listing. For example, if you want to restrict the IP addresses the server uses for listening, you would do that in an *OnListening* event handler.

Events with client connections

When a server socket accepts a client connection request, the following events occur:

- An OnAccept event occurs, passing in the new *TTcpClient* object to the event handler. This is the first point when you can use the properties of *TTcpClient* to obtain information about the server endpoint of the connection to a client.
- If BlockMode is *bmThreadBlocking* an OnGetThread event occurs. If you want to provide your own customized descendant of ServerSocketThread, you can create one in an *OnGetThread* event handler, and that will be used instead of *TServerSocketThread*. If you want to perform any initialization of the thread, or make any socket API calls before the thread starts reading or writing over the connection, you should use the *OnGetThread* event handler for these tasks as well.
- The client completes the connection and an OnAccept event occurs. With a non-blocking server, you may want to start reading or writing over the socket connection at this point.

Types of Socket Connections (see page 2345)

3.2.5.6.6 Types of socket connections

Topics

Name	Description
Client Connections (see page 2344)	Client connections connect a client socket on the local system to a server socket on a remote system. Client connections are initiated by the client socket. First, the client socket must describe the server socket to which it wishes to connect. The client socket then looks up the server socket and, when it locates the server, requests a connection. The server socket may not complete the connection right away. Server sockets maintain a queue of client requests, and complete connections as they find time. When the server socket accepts the client connection, it sends the client socket a full description... more (see page 2344)
Listening Connections (see page 2345)	Server sockets do not locate clients. Instead, they form passive "half connections" that listen for client requests. Server sockets associate a queue with their listening connections; the queue records client connection requests as they come in. When the server socket accepts a client connection request, it forms a new socket to connect to the client, so that the listening connection can remain open to accept other client requests.
Server Connections (see page 2345)	Server connections are formed by server sockets when a listening socket accepts a client request. A description of the server socket that completes the connection to the client is sent to the client when the server accepts the connection. The connection is established when the client socket receives this description and completes the connection.
Types of Socket Connections (see page 2345)	Socket connections can be divided into three basic types, which reflect how the connection was initiated and what the local socket is connected to. These are • Client connections (see page 2344). • Listening connections (see page 2345). • Server connections (see page 2345). Once the connection to a client socket is completed, the server connection is indistinguishable from a client connection. Both end points have the same capabilities and receive the same types of events. Only the listening connection is fundamentally different, as it has only a single endpoint.

3.2.5.6.6.1 Client Connections

Client connections connect a client socket on the local system to a server socket on a remote system. Client connections are initiated by the client socket. First, the client socket must describe the server socket to which it wishes to connect. The client socket then looks up the server socket and, when it locates the server, requests a connection. The server socket may not complete the connection right away. Server sockets maintain a queue of client requests, and complete connections as they find time. When the server socket accepts the client connection, it sends the client socket a full description of the server socket to which it is connecting, and the connection is completed by the client.

Listening Connections (see page 2345)

Server Connections (see page 2345)

Using Client Sockets (see page 2348)

Client Events (see page 2342)

3.2.5.6.6.2 Listening Connections

Server sockets do not locate clients. Instead, they form passive "half connections" that listen for client requests. Server sockets associate a queue with their listening connections; the queue records client connection requests as they come in. When the server socket accepts a client connection request, it forms a new socket to connect to the client, so that the listening connection can remain open to accept other client requests.

3.2.5.6.7 Using socket components

Topics

Name	Description
Using client sockets (see page 2346)	
Using Socket Components (see page 2348)	The Internet category includes three socket components that allow your network application to form connections to other machines, and that allow you to read and write information over that connection. These are: • TTcpServer • TTcpClient • TUdpSocket Associated with each of these socket components are socket objects, which represent the endpoint of an actual socket connection. The socket components use the socket objects to encapsulate the socket server calls, so that your application does not need to be concerned with the details of establishing the connection or managing the socket messages. If you want to customize the details of the connections that... more (see page 2348)
Using server sockets (see page 2349)	
Getting Information About the Client or Server Socket Connection (see page 2351)	After completing the connection to a client or server socket, you can use the client or server socket object associated with your socket component to obtain information about the connection. Use the LocalHost and LocalPort properties to determine the address and port number used by the local client or server socket, or use the RemoteHost and RemotePort properties to determine the address and port number used by the remote client or server socket. Use the GetSocketAddr method to build a valid socket address based on the host name and port number. You can use the LookupPort method to look up... more (see page 2351)

3.2.5.6.7.1 Using client sockets

Topics

Name	Description
Closing the Connection (see page 2347)	When you have finished communicating with a server application over the socket connection, you can shut down the connection by calling the Close method. The connection may also be closed from the server end. If that is the case, you will receive notification in an OnDisconnect event.
Forming the Connection (see page 2347)	Once you have set the properties of your client socket component to describe the server you want to connect to, you can form the connection at runtime by calling the Open method. If you want your application to form the connection automatically when it starts up, set the Active property to *True* at design time, using the **Object Inspector**.
Getting Information About the Client Socket Connection (see page 2347)	After completing the connection to a server socket, you can use the client socket object associated with your client socket component to obtain information about the connection. Use the LocalHost and LocalPort properties to determine the address and port number used by the client and server sockets to form the end points of the connection. You can use the Handle property to obtain a handle to the socket connection to use when making socket calls.

Specifying the Desired Server (see page 2348)	Client socket components have a number of properties that allow you to specify the server system and port to which you want to connect. Use the RemoteHost property to specify the remote host server by either its host name or IP address. In addition to the server system, you must specify the port on the server system that your client socket will connect to. You can use the RemotePort property to specify the server port number directly or indirectly by naming the target service.
Using Client Sockets (see page 2348)	Add a TTcpClient or TUdpSocket component to your form or data module to turn your application into a TCP/IP or UDP client. Client sockets allow you to specify the server socket you want to connect to, and the service you want that server to provide. Once you have described the desired connection, you can use the client socket component to complete the connection to the server. Each client socket component uses a single client socket object to represent the client endpoint in a connection. Use client sockets to • Specify the desired server (see page 2348). • Connect to the server (see page 2347). • Get information (see page 2347)... more (see page 2348)

3.2.5.6.7.1.1 Closing the Connection

When you have finished communicating with a server application over the socket connection, you can shut down the connection by calling the Close method. The connection may also be closed from the server end. If that is the case, you will receive notification in an OnDisconnect event.

Reading and Writing Over Socket Connections (see page 2341)

Closing the Connection (see page 2347)

Describing Sockets (see page 2336)

3.2.5.6.7.1.5 Using Client Sockets

Add a TTcpClient or TUdpSocket component to your form or data module to turn your application into a TCP/IP or UDP client. Client sockets allow you to specify the server socket you want to connect to, and the service you want that server to provide. Once you have described the desired connection, you can use the client socket component to complete the connection to the server.

Each client socket component uses a single client socket object to represent the client endpoint in a connection.

Use client sockets to

- Specify the desired server (see page 2348).
- Connect to the server (see page 2347).
- Get information about the connection (see page 2347).
- Read from or write to the server (see page 2341).
- Close the connection (see page 2347).

3.2.5.6.7.3 Using server sockets

Topics

Name	Description
Closing Server Connections (see page 2349)	When you want to shut down the listening connection, call the Close method or set the Active property to *False*. This shuts down all open connections to client applications, cancels any pending connections that have not been accepted, and then shuts down the listening connection so that your server socket component does not accept any new connections. When TCP clients shut down their individual connections to your server socket, you are informed by an OnDisconnect event.
Connecting to Clients (see page 2350)	A listening server socket component automatically accepts client connection requests when they are received. You receive notification every time this occurs in an OnAccept event.
Listening for Client Requests (see page 2350)	Once you have set the port number of your server socket component, you can form a listening connection at runtime by calling the Open method. If you want your application to form the listening connection automatically when it starts up, set the Active property to *True* at design time, using the **Object Inspector**.
Specifying the Port (see page 2350)	Before your server socket can listen to client requests, you must specify the port that your server will listen on. You can specify this port using the LocalPort property. If your server application is providing a standard service that is associated by convention with a specific port number, you can also specify the service name using the *LocalPort* property. It is a good idea to use the service name instead of a port number, because it is easy to introduce typographical errors when specifying the port number.
Using Server Sockets (see page 2351)	Add a server socket component (TTcpServer or TUdpSocket) to your form or data module to turn your application into an IP server. Server sockets allow you to specify the service you are providing or the port you want to use to listen for client requests. You can use the server socket component to listen for and accept client connection requests. Each server socket component uses a single server socket object to represent the server endpoint in a listening connection. It also uses a server client socket object for the server endpoint of each active connection to a client socket that... more (see page 2351)

3.2.5.6.7.3.1 Closing Server Connections

When you want to shut down the listening connection, call the Close method or set the Active property to *False*. This shuts down all open connections to client applications, cancels any pending connections that have not been accepted, and then shuts down the listening connection so that your server socket component does not accept any new connections.

When TCP clients shut down their individual connections to your server socket, you are informed by an OnDisconnect event.

Connecting to Clients (see page 2350)

Reading and Writing Over Socket Connections (see page 2341)

Closing Server Connections (see page 2349)

Services and Ports (see page 2339)

3.2.5.6.7.3.5 Using Server Sockets

Add a server socket component (TTcpServer or TUdpSocket) to your form or data module to turn your application into an IP server. Server sockets allow you to specify the service you are providing or the port you want to use to listen for client requests. You can use the server socket component to listen for and accept client connection requests.

Each server socket component uses a single server socket object to represent the server endpoint in a listening connection. It also uses a server client socket object for the server endpoint of each active connection to a client socket that the server accepts.

Use server sockets to

- Specify the port (see page 2350).
- Listen for client requests (see page 2350).
- Connect to clients (see page 2350).
- Read from or write to the server (see page 2341).
- Close server connections (see page 2349).

Server Events (see page 2343)

3.2.5.6.7.4 Getting Information About the Client or Server Socket Connection

After completing the connection to a client or server socket, you can use the client or server socket object associated with your socket component to obtain information about the connection. Use the LocalHost and LocalPort properties to determine the address and port number used by the local client or server socket, or use the RemoteHost and RemotePort properties to determine the address and port number used by the remote client or server socket. Use the GetSocketAddr method to build a valid socket address based on the host name and port number. You can use the LookupPort method to look up the port number. Use the LookupProtocol method to look up the protocol number. Use the LookupHostName method to look up the host name based on the host machine's IP address.

To view network traffic in and out of the socket, use the BytesSent and BytesReceived properties.

3.2.5.7 Working with XML documents

Topics

Name	Description
Working with XML Documents (see page 2352)	XML (Extensible Markup Language) is a markup language for describing structured data. It is similar to HTML, except that the tags describe the structure of information rather than its display characteristics. XML documents provide a simple, text-based way to store information so that it is easily searched or edited. They are often used as a standard, transportable format for data in Web applications, business-to-business communication, and so on. XML documents provide a hierarchical view of a body of data. Tags in the XML document describe the role or meaning of each data element, as illustrated in the following document, which... more (see page 2352)

Using the Document Object Model (see page 2353)	The Document Object Model (DOM) is a set of standard interfaces for representing a parsed XML document. These interfaces are implemented by a number of different third-party vendors. If you do not want to use the default vendor that ships with Delphi, there is a registration mechanism that lets you integrate additional DOM implementations by other vendors into the XML framework. The XMLDOM unit includes declarations for all the DOM interfaces defined in the W3C XML DOM level 2 specification. Each DOM vendor provides an implementation for these interfaces. • To use one of the DOM vendors for which Delphi already... more (see page 2353)
Working with XML Components (see page 2354)	The VCL defines a number of classes and interfaces for working with XML documents. These simplify the process of loading, editing, and saving XML documents. To use the XML classes for examining or editing an XML document you start by setting up an instance of TXMLDocument (see page 2354). You can then work with the nodes (see page 2355) of the XML document component to examine or edit the body of the XML document.
Using TXMLDocument (see page 2354)	The starting point for working with an XML document is the TXMLDocument component.
Working with XML Nodes (see page 2355)	Once an XML document has been parsed by a DOM implementation, the data it represents is available as a hierarchy of nodes. Each node corresponds to a tagged element in the document. For example, given the following XML:
Abstracting XML Documents with the Data Binding Wizard (see page 2356)	It is possible to work with an XML document using only the *TXMLDocument* component and the *IXMLNode* interface it surfaces for the nodes in that document, or even to work exclusively with the DOM interfaces (avoiding even *TXMLDocument*). However, you can write code that is much simpler and more readable by using the XML Data Binding wizard. The Data Binding wizard takes an XML schema or data file and generates a set of interfaces that map on top of it. For example, given XML data that looks like the following:
Using the XML Data Binding Wizard (see page 2358)	
Using Code That the XML Data Binding Wizard Generates (see page 2359)	Once the wizard has generated a set of interfaces and implementation classes, you can use them to work with XML documents that match the structure of the document or schema you supplied to the wizard. Just as when you are using only the built-in XML components (see page 2354), your starting point is the TXMLDocument component that appears on the Internet category of the **Tool Palette**.

3.2.5.7.1 Working with XML Documents

XML (Extensible Markup Language) is a markup language for describing structured data. It is similar to HTML, except that the tags describe the structure of information rather than its display characteristics. XML documents provide a simple, text-based way to store information so that it is easily searched or edited. They are often used as a standard, transportable format for data in Web applications, business-to-business communication, and so on.

XML documents provide a hierarchical view of a body of data. Tags in the XML document describe the role or meaning of each data element, as illustrated in the following document, which describes a collection of stock holdings:

```
<?xml version="1.0" encoding="UTF-8" standalone="no" ?>
<!DOCTYPE StockHoldings SYSTEM "sth.dtd">
<StockHoldings>
   <Stock exchange="NASDAQ">
      <name>Borland</name>
      <price>15.375</price>
      <symbol>BORL</symbol>
      <shares>100</shares>
   </Stock>
   <Stock exchange="NYSE">
      <name>Pfizer</name>
      <price>42.75</price>
      <symbol>PFE</symbol>
      <shares type="preferred">25</shares>
   </Stock>
</StockHoldings>
```

This example illustrates a number of typical elements in an XML document. The first line is a processing instruction called an XML declaration. The XML declaration is optional but you should include it, because it supplies useful information about the document. In this example, the XML declaration says that the document conforms to version 1.0 of the XML specification, that it uses UTF-8 character encoding, and that it relies on an external file for its document type declaration (DTD).

The second line, which begins with the <!DOCType> tag, is a document type declaration (DTD). The DTD is how XML defines the structure of the document. It imposes syntax rules on the elements (tags) contained in the document. The DTD in this example references another file (sth.dtd). In this case, the structure is defined in an external file, rather than in the XML document itself. Other types of files that describe the structure of an XML document include Reduced XML Data (XDR) and XML schemas (XSD).

The remaining lines are organized into a hierarchy with a single root node (the <StockHoldings> tag). Each node in this hierarchy contains either a set of child nodes, or a text value. Some of the tags (the <Stock> and <shares> tags) include attributes, which are Name=Value pairs that provide details on how to interpret the tag.

Although it is possible to work directly with the text in an XML document, typically applications use additional tools for parsing and editing the data. W3C defines a set of standard interfaces for representing a parsed XML document called the Document Object Model (DOM) (see page 2353). A number of vendors provide XML parsers that implement the DOM interfaces to let you interpret and edit XML documents more easily.

Delphi provides a number of additional tools for working with XML documents. These tools use a DOM parser that is provided by another vendor, and make it even easier to work with XML documents.They include

- VCL components and interfaces (see page 2354) for working with XML documents.
- An XML Data Binding wizard (see page 2356) for generating classes to represent a particular XML document.
- Tools and components for converting between XML documents and data packets (see page 1847), which let you integrate XML documents into database applications.

See Also

Using XML in Database Applications (see page 1847)

3.2.5.7.2 Using the Document Object Model

The Document Object Model (DOM) is a set of standard interfaces for representing a parsed XML document. These interfaces are implemented by a number of different third-party vendors. If you do not want to use the default vendor that ships with Delphi, there is a registration mechanism that lets you integrate additional DOM implementations by other vendors into the XML framework.

The XMLDOM unit includes declarations for all the DOM interfaces defined in the W3C XML DOM level 2 specification. Each DOM vendor provides an implementation for these interfaces.

- To use one of the DOM vendors for which Delphi already includes support, locate the unit that represents the DOM implementation. These units end in the string 'xmldom.' For example, the unit for the Microsoft implementation is MSXMLDOM, the unit for the Xerces implementation is XERCESXMLDOM, and the unit for the Open XML implementation is OXMLDOM. If you add the unit for the desired implementation to your project, the DOM implementation is automatically registered so that it is available to your code.
- To use another DOM implementation, you must create a unit that defines a descendant of the TDOMVendor class. This unit can then work like one of the built-in DOM implementations, making your DOM implementation available when it is included in a project.
- In your descendant class, you must override two methods: the *Description* method, which returns a string identifying the vendor, and the *DOMImplementation* method, which returns the top-level interface (*IDOMImplementation*).
- Your new unit must register the vendor by calling the global RegisterDOMVendor procedure. This call typically goes in the initialization section of the unit.
- When your unit is unloaded, it needs to unregister itself to indicate that the DOM implementation is no longer available.

Unregister the vendor by calling the global UnRegisterDOMVendor procedure. This call typically goes in the finalization section.

Some vendors supply extensions to the standard DOM interfaces. To allow you to uses these extensions, the XMLDOM unit also defines an *IDOMNodeEx* interface. *IDOMNodeEx* is a descendant of the standard *IDOMNode* that includes the most useful of these extensions.

You can work directly with the DOM interfaces to parse and edit XML documents. Simply call the GetDOM function to obtain an *IDOMImplementation* interface, which you can use as a starting point.

Note: For detailed descriptions of the DOM interfaces, see the declarations in the XMLDOM unit, the documentation supplied by your DOM Vendor, or the specifications provided on the W3C web site (www.w3.org).

You may find it more convenient to use special XML classes rather than working directly with the DOM interfaces. These are described in:

- Working with XML components (see page 2354)
- Abstracting XML documents with the Data Binding wizard (see page 2356)

Using XML in Database Applications (see page 1847)

3.2.5.7.3 Working with XML Components

The VCL defines a number of classes and interfaces for working with XML documents. These simplify the process of loading, editing, and saving XML documents.

To use the XML classes for examining or editing an XML document you start by setting up an instance of TXMLDocument (see page 2354). You can then work with the nodes (see page 2355) of the XML document component to examine or edit the body of the XML document.

See Also

Using XML in Database Applications (see page 1847)

Using the Document Object Model (see page 2353)

3.2.5.7.4 Using TXMLDocument

The starting point for working with an XML document is the TXMLDocument component.

The following steps describe how to use TXMLDocument to work directly with an XML document:

1. Add a *TXMLDocument* component to your form or data module. *TXMLDocument* appears on the Internet category of the **Tool Palette**.
2. Set the DOMVendor property to specify the DOM implementation you want the component to use for parsing and editing an XML document. The **Object Inspector** lists all the currently registered DOM vendors. For information on DOM implementations, see Using the Document Object Model (see page 2353).
3. Depending on your implementation, you may want to set the ParseOptions property to configure how the underlying DOM implementation parses the XML document.
4. If you are working with an existing XML document, specify the document:

- If the XML document is stored in a file, set the FileName property to the name of that file.
- You can specify the XML document as a string instead by using the XML property.

5. Set the Active property to *True*.

Once you have an active *TXMLDocument* object, you can traverse the hierarchy of its nodes, reading or setting their values. The root node of this hierarchy is available as the DocumentElement property.

For information on working with the nodes of the XML document, see Working with XML nodes (see page 2355).

See Also

Using the Document Object Model (see page 2353)

3.2.5.7.5 Working with XML Nodes

Once an XML document has been parsed by a DOM implementation, the data it represents is available as a hierarchy of nodes. Each node corresponds to a tagged element in the document. For example, given the following XML:

```
<?xml version="1.0" encoding="UTF-8" standalone="no" ?>
<!DOCTYPE StockHoldings SYSTEM "sth.dtd">
<StockHoldings>
   <Stock exchange="NASDAQ">
      <name>Borland</name>
      <price>15.375</price>
      <symbol>BORL</symbol>
      <shares>100</shares>
   </Stock>
   <Stock exchange="NYSE">
      <name>Pfizer</name>
      <price>42.75</price>
      <symbol>PFE</symbol>
      <shares type="preferred">25</shares>
   </Stock>
</StockHoldings>
```

TXMLDocument would generate a hierarchy of nodes as follows: The root of the hierarchy would be the *StockHoldings* node. *StockHoldings* would have two child nodes, which correspond to the two *Stock* tags. Each of these two child nodes would have four child nodes of its own (*name*, *price*, *symbol*, and *shares*). Those four child nodes would act as leaf nodes. The text they contain would appear as the value of each of the leaf nodes.

Note: This division into nodes differs slightly from the way a DOM implementation generates nodes for an XML document. In particular, a DOM parser treats all tagged elements as internal nodes. Additional nodes (of type text node) are created for the values of the *name*, *price*, *symbol*, and *shares* nodes. These text nodes then appear as the children of the *name*, *price*, *symbol*, and *shares* nodes.

Each node is accessed through an IXMLNode interface, starting with the root node, which is the value of the XML document component's DocumentElement property.

Working with a node's value

Given an *IXMLNode* interface, you can check whether it represents an internal node or a leaf node by checking the IsTextElement property.

- If it represents a leaf node, you can read or set its value using the Text property.
- If it represents an internal node, you can access its child nodes using the ChildNodes property.

Thus, for example, using the XML document above, you can read the price of Borland's stock as follows:

```
BorlandStock := XMLDocument1.DocumentElement.ChildNodes[0];
Price := BorlandStock.ChildNodes['price'].Text;
_di_IXMLNode BorlandStock = XMLDocument1->DocumentElement->ChildNodes->GetNode(0);
AnsiString Price = BorlandStock->ChildNodes->Nodes[WideString("price")]->Text;
```

Working with a node's attributes

If the node includes any attributes, you can work with them using the Attributes property. You can read or change an attribute value by specifying an existing attribute name. You can add new attributes by specifying a new attribute name when you set the *Attributes* property:

```
BorlandStock := XMLDocument1.DocumentElement.ChildNodes[0];
```

```
BorlandStock.ChildNodes['shares'].Attributes['type'] := 'common';
_di_IXMLNode BorlandStock = XMLDocument1->DocumentElement->ChildNodes->GetNode(0);
BorlandStock->ChildNodes->Nodes[WideString("shares")]->Attributes[WideString("type")] =
"common";
```

Adding and deleting child nodes

You can add child nodes using the *AddChild* method. AddChild creates new nodes that correspond to tagged elements in the XML document. Such nodes are called element nodes.

To create a new element node, specify the name that appears in the new tag and, optionally, the position where the new node should appear. For example, the following code adds a new stock listing to the document above:

```
var
  NewStock: IXMLNode;
  ValueNode: IXMLNode;
begin
  NewStock := XMLDocument1.DocumentElement.AddChild('stock');
  NewStock.Attributes['exchange'] := 'NASDAQ';
  ValueNode := NewStock.AddChild('name');
  ValueNode.Text := 'Cisco Systems'
  ValueNode := NewStock.AddChild('price');
  ValueNode.Text := '62.375';
  ValueNode := NewStock.AddChild('symbol');
  ValueNode.Text := 'CSCO';
  ValueNode := NewStock.AddChild('shares');
  ValueNode.Text := '25';
end;
_di_IXMLNode NewStock = XMLDocument1->DocumentElement->AddChild(WideString("stock"));
NewStock->Attributes[WideString("exchange")] = "NASDAQ";
_di_IXMLNode ValueNode = NewStock->AddChild(WideString("name"));
ValueNode->Text = WideString("Cisco Systems");
ValueNode = NewStock->AddChild(WideString("price"));
ValueNode->Text = WideString("62.375");
ValueNode = NewStock->AddChild(WideString("symbol"));
ValueNode->Text = WideString("CSCO");
ValueNode = NewStock->AddChild(WideString("shares"));
ValueNode->Text = WideString("25");
```

An overloaded version of *AddChild* lets you specify the namespace URI in which the tag name is defined.

You can delete child nodes using the methods of the *ChildNodes* property. ChildNodes is an *IXMLNodeList* interface, which manages the children of a node. You can use its Delete method to delete a single child node that is identified by position or by name. For example, the following code deletes the last stock listed in the document above:

```
StockList := XMLDocument1.DocumentElement;
StockList.ChildNodes.Delete(StockList.ChildNodes.Count - 1);
_di_IXMLNode StockList = XMLDocument1->DocumentElement;
StockList->ChildNodes->Delete(StockList->ChildNodes->Count - 1);
```

See Also

Using TXMLDocument (see page 2354)

Using the Document Object Model (see page 2353)

3.2.5.7.6 Abstracting XML Documents with the Data Binding Wizard

It is possible to work with an XML document using only the *TXMLDocument* component and the *IXMLNode* interface it surfaces for the nodes in that document, or even to work exclusively with the DOM interfaces (avoiding even *TXMLDocument*). However, you can write code that is much simpler and more readable by using the XML Data Binding wizard.

The Data Binding wizard takes an XML schema or data file and generates a set of interfaces that map on top of it. For example, given XML data that looks like the following:

```
<customer id=1>
  <name>Mark</name>
  <phone>(831) 431-1000</phone>
</customer>
```

The Data Binding wizard generates the following interface (along with a class to implement it):

```
ICustomer = interface(IXMLNode)
        ['{8CD6A6E8-24FC-426F-9718-455F0C507C8E}']
        { Property Accessors }
        function Get_Id: Integer;
        function Get_Name: WideString;
        function Get_Phone: WideString;
        procedure Set_Id(Value: Integer);
        procedure Set_Name(Value: WideString);
        procedure Set_Phone(Value: WideString);
        { Methods & Properties }
        property Id: Integer read Get_Id write Set_Id;
        property Name: WideString read Get_Name write Set_Name;
        property Phone: WideString read Get_Phone write Set_Phone;
end;
__interface INTERFACE_UUID("{F3729105-3DD0-1234-80e0-22A04FE7B451}") ICustomer :
    public IXMLNode
{
public:
  virtual int __fastcall Getid(void) = 0 ;
  virtual DOMString __fastcall Getname(void) = 0 ;
  virtual DOMString __fastcall Getphone(void) = 0 ;
  virtual void __fastcall Setid(int Value)= 0 ;
  virtual void __fastcall Setname(DOMString Value)= 0 ;
  virtual void __fastcall Setphone(DOMString Value)= 0 ;
  __property int id = {read=Getid, write=Setid};
  __property DOMString name = {read=Getname, write=Setname};
  __property DOMString phone = {read=Getphone, write=Setphone};
};
```

Every child node is mapped to a property whose name matches the tag name of the child node and whose value is the interface of the child node (if the child is an internal node) or the value of the child node (for leaf nodes). Every node attribute is also mapped to a property, where the property name is the attribute name and the property value is the attribute value.

In addition to creating interfaces (and implementation classes) for each tagged element in the XML document, the wizard creates global functions for obtaining the interface to the root node. For example, if the XML above came from a document whose root node had the tag <Customers>, the Data Binding wizard would create the following global routines:

```
function Getcustomers(Doc: IXMLDocument): IXMLCustomerType;
function Loadcustomers(const FileName: WideString): IXMLCustomerType;
function Newcustomers: IXMLCustomerType;
extern PACKAGE _di_ICustomers __fastcall GetCustomers(TXMLDocument *XMLDoc);
extern PACKAGE _di_ICustomers __fastcall GetCustomers(_di_IXMLDocument XMLDoc);
extern PACKAGE _di_ICustomers __fastcall LoadCustomers(const WideString FileName);
extern PACKAGE _di_ICustomers __fastcall NewCustomers(void);
```

The Get... function takes the interface for a *TXMLDocument* instance . The Load... function dynamically creates a *TXMLDocument* instance and loads the specified XML file as its value before returning an interface pointer. The New... function creates a new (empty) *TXMLDocument* instance and returns the interface to the root node.

Using the generated interfaces simplifies your code, because they reflect the structure of the XML document more directly. For example, instead of writing code such as the following:

```
CustIntf := XMLDocument1.DocumentElement;
CustName := CustIntf.ChildNodes[0].ChildNodes['name'].Value;
_di_IXMLNode CustIntf = XMLDocument1->DocumentElement;
CustName =
CustIntf->ChildNodes->Nodes->GetNode(0)->ChildNodes->Nodes[WideString("name")]->Value;
```

Your code would look as follows:

```
CustIntf := GetCustomers(XMLDocument1);
CustName := CustIntf[0].Name;
_di_ICustomers CustIntf = GetCustomers(XMLDocument1);
CustName = CustIntf->Nodes->GetNode(0)->Name;
```

Note that the interfaces generated by the Data Binding wizard all descend from *IXMLNode*. This means you can still add and delete child nodes in the same way as when you do not use the Data Binding wizard. (See the Adding and deleting child nodes section of Working with XML Nodes (see page 2355).) In addition, when child nodes represent repeating elements (when all of the children of a node are of the same type), the parent node is given two methods, *Add*, and *Insert*, for adding additional repeats. These methods are simpler than using *AddChild*, because you do not need to specify the type of node to create.

The following topics provide detailed information on using the XML Data Binding wizard:

- Using the XML Data Binding wizard (see page 2358)
- Using code that the XML Data Binding wizard generates (see page 2359)

Using the Document Object Model (see page 2353)

Working with XML Components (see page 2354)

3.2.5.7.7 Using the XML Data Binding Wizard

To use the Data Binding wizard:

1. Choose **File** ▸ **New** ▸ **Other** and select the icon labeled XML Data Binding from the right pane of the New folder located under Delphi Projects.
2. The XML Data Binding wizard appears.
3. On the first page of the wizard, specify the XML document or schema for which you want to generate interfaces. This can be a sample XML document, a Document Type Definition (.dtd) file, a Reduced XML Data (.xdr) file, or an XML schema (.xsd) file.
4. Click the Options button to specify the naming strategies you want the wizard to use when generating interfaces and implementation classes and the default mapping of types defined in the schema to native Delphi data types.
5. Move to the second page of the wizard. This page lets you provide detailed information about every node type in the document or schema. At the left is a tree view that shows all of the node types in the document. For complex nodes (nodes that have children), the tree view can be expanded to display the child elements. When you select a node in this tree view, the right-hand side of the dialog displays information about that node and lets you specify how you want the wizard to treat that node.

- The Source Name control displays the name of the node type in the XML schema.
- The Source Datatype control displays the type of the node's value, as specified in the XML schema.
- The Documentation control lets you add comments to the schema describing the use or purpose of the node.
- If the wizard generates code for the selected node (that is, if it is a complex type for which the wizard generates an interface and implementation class, or if it is one of the child elements of a complex type for which the wizard generates a property on the complex type's interface), you can use the Generate Binding check box to specify whether you want the wizard to generate code for the node. If you uncheck Generate Binding, the wizard does not generate the interface or implementation class for a complex type, or does not create a property in the parent interface for a child element or attribute.
- The Binding Options section lets you influence the code that the wizard generates for the selected element. For any node, you can specify the Identifier Name (the name of the generated interface or property). In addition, for interfaces, you must indicate which one represents the root node of the document. For nodes that represent properties, you can specify the type of the property and, if the property is not an interface, whether it is a read-only property.

6. Once you have specified what code you want the wizard to generate for each node, move to the third page. This page lets you choose some global options about how the wizard generates its code and lets you preview the code that will be generated, and lets you tell the wizard how to save your choices for future use.

- To preview the code the wizard generates, select an interface in the Binding Summary list and view the resulting interface definition in the Code Preview control.
- Use the Data Binding Settings to indicate how the wizard should save your choices. You can store the settings as annotations in a schema file that is associated with the document (the schema file specified on the first page of the dialog), or you can name an independent schema file that is used only by the wizard.

7. When you click Finish, the Data Binding wizard generates a new unit that defines interfaces and implementation classes for all of the node types in your XML document. In addition, it creates a global function that takes a *TXMLDocument* object and returns the interface for the root node of the data hierarchy.

See Also

Using Code That the XML Data Binding Wizard Generates (see page 2359)

3.2.5.7.8 Using Code That the XML Data Binding Wizard Generates

Once the wizard has generated a set of interfaces and implementation classes, you can use them to work with XML documents that match the structure of the document or schema you supplied to the wizard. Just as when you are using only the built-in XML components (see page 2354), your starting point is the TXMLDocument component that appears on the Internet category of the **Tool Palette**.

To work with an XML document, use the following steps:

1. Obtain an interface for the root node of your XML document. You can do this in one of three ways:

Method	Description
Place a *TXMLDocument* component in your form or data module. Bind the *TXMLDocument* to an XML document by setting the FileName property.	(As an alternative approach, you can use a string of XML by setting the XML property at runtime.) Then, In your code, call the global function that the wizard created to obtain an interface for the root node of the XML document. For example, if the root element of the XML document was the tag <StockList>, by default, the wizard generates a function *Getstocklist*, which returns an *IXMLStockListType*. interface: var StockList: IXMLStockListType; begin XMLDocument1.FileName := 'Stocks.xml'; StockList := Getstocklist(XMLDocument1); XMLDocument1->FileName := "Stocks.xml"; _di_IStockListType StockList = GetStockListType(XMLDocument1);
Call the generated Load... function	Call the generated Load... function to create and bind the *TXMLDocument* instance and obtain its interface all in one step. For example, using the same XML document described above: var StockList: IXMLStockListType; begin StockList := Loadstocklist('Stocks.xml'); _di_IStockListType StockList = LoadStockListType("Stocks.xml");
Call the generated New... function	Call the generated New... function to create the *TXMLDocument* instance for an empty document when you want to create all the data in your application: var StockList: IXMLStockListType; begin StockList := Newstocklist; _di_IStockListType StockList = NewStockListType();

2. This interface has properties that correspond to the subnodes of the document's root element, as well as properties that correspond to that root element's attributes. You can use these to traverse the hierarchy of the XML document, modify the data in the document, and so on.
3. To save any changes you make using the interfaces generated by the wizard, call the *TXMLDocument* component's SaveToFile method or read its XML property.

   Tip: If you set the *Options* property of the *TXMLDocument* object to include *doAutoSave*, then you do not need to explicitly call the *SaveToFile* method.

E

E2000: 286/287 instructions not enabled (C++) 286
E2001: Constructors and destructors not allowed in __automated section (C++) 289

E2002: Only __fastcall functions allowed in __automated section (C++) 289

E2003: Data member definition not allowed in __automated section (C++) 289

E2004: Only read or write clause allowed in property declaration in __automated section (C++) 289

E2005: Redeclaration of property not allowed in __automated section (C++) 290

E2006: CodeGuarded programs must use the large memory model and be targeted for Windows (C++) 342

E2007: Dispid only allowed in __automated sections (C++) 309

E2008: Published property access functions must use __fastcall calling convention (C++) 257

E2009: Attempt to grant or reduce access to 'identifier' (C++) 286

E2010: Cannot add or subtract relocatable symbols (C++) 287

E2011: Illegal to take address of bit field (C++) 286

E2012: Cannot take address of 'main' (C++) 344

E2013: 'function1' cannot be distinguished from 'function2' (C++) 287

E2014: Member is ambiguous: 'member1' and 'member2' (C++) 287

E2015: Ambiguity between 'function1' and 'function2' (C++) 287

E2016: Ambiguous override of virtual base member 'base_function': 'derived_function' (C++) 344

E2017: Ambiguous member name 'name' (C++) 287

E2018: Cannot catch 'identifier' -- ambiguous base class 'identifier' (C++) 380

E2019: 'identifier' cannot be declared in an anonymous union (C++) 288

E2020: Global anonymous union not static (C++) 288

E2021: Array must have at least one element (C++) 344

E2022: Array size too large (C++) 288

E2023: Array of references is not allowed (C++) 344

E2024: Cannot modify a const object (C++) 288

E2025: Assignment to 'this' not allowed, use X::operator new instead (C++) 288

E2026: Assembler statement too long (C++) 288

E2027: Must take address of a memory location (C++) 290

E2028: operator -> must return a pointer or a class (C++) 290

E2029: 'identifier' must be a previously defined class or struct (C++) 290

E2030: Misplaced break (C++) 290

E2031: Cannot cast from 'type1' to 'type2' (C++) 290

E2032: Illegal use of closure pointer (C++) 344

E2033: Misplaced continue (C++) 291

E2034: Cannot convert 'type1' to 'type2' (C++) 291

E2035: Conversions of class to itself or base class not allowed (C++) 304

E2036: Conversion operator cannot have a return type specification (C++) 292

E2037: The constructor 'constructor' is not allowed (C++) 292

E2038: Cannot declare or define 'identifier' here: wrong namespace (C++) 304

E2039: Misplaced decimal point (C++) 292

E2040: Declaration terminated incorrectly (C++) 345

E2041: Incorrect use of default (C++) 292

E2042: Declare operator delete (void*) or (void*, size_t) (C++) 293

E2044: operator delete must return void (C++) 293

E2045: Destructor name must match the class name (C++) 293

E2046: Bad file name format in include directive OR Bad file name format in line directive (C++) 294

E2047: Bad 'directive' directive syntax (C++) 345

E2048: Unknown preprocessor directive: 'identifier' (C++) 293

E2049: Class type 'type' cannot be marked as __declspec(delphireturn) (C++) 345

E2050: __declspec(delphireturn) class 'class' must have exactly one data member (C++) 258

E2051: Invalid use of dot (C++) 294

E2052: Dynamic function 'function' conflicts with base class 'class' (C++) 345

E2053: Misplaced elif directive (C++) 294

E2054: Misplaced else (C++) 294

E2055: Misplaced else directive (C++) 294

E2056: Misplaced endif directive (C++) 295

E2057: Exception specification not allowed here (C++) 345

E2058: Exception handling variable may not be used here (C++) 346

E2059: Unknown language, must be C or C++ (C++) 295

E2060: Illegal use of floating point (C++) 295

E2061: Friends must be functions or classes (C++) 295

E2062: Invalid indirection (C++) 295

E2063: Illegal initialization (C++) 296

E2064: Cannot initialize 'type1' with 'type2' (C++) 296

E2065: Using namespace symbol 'symbol' conflicts with intrinsic of the same name (C++) 346

E2066: Information not available (C++) 261

E2066: Invalid MOM inheritance (C++) 256

E2067: 'main' must have a return type of int (C++) 346

E2068: 'identifier' is not a non-static data member and can't be initialized here (C++) 296

E2069: Illegal use of member pointer (C++) 296

E2070: Invalid use of namespace 'identifier' (C++) 315

E2071: operator new must have an initial parameter of type size_t (C++) 297

E2072: Operator new[] must return an object of type void (C++) 297

E2073: Nothing allowed after pragma option pop (C++) 346

E2074: Value after -g or -j should be between 0 and 255 inclusive (C++) 259

E2075: Incorrect 'type' option: option (C++) 297

E2076: Overloadable operator expected (C++) 297

E2077: 'operator' must be declared with one or no parameters (C++) 298

E2078: 'operator' must be declared with one or two parameters (C++) 298

E2079: 'function' must be declared with no parameters (C++) 298

E2080: 'function' must be declared with one parameter (C++) 298

E2081: 'function' must be declared with two parameters (C++) 298

E2082: 'identifier' must be a member function or have a parameter of class type (C++) 298

E2083: Last parameter of 'operator' must have type 'int' (C++) 299

E2084: Parameter names are used only with a function body (C++) 299

E2085: Invalid pointer addition (C++) 299

E2086: Illegal pointer subtraction (C++) 299

E2087: Illegal use of pointer (C++) 299

E2088: Bad syntax for pure function definition (C++) 300

E2089: Identifier 'identifier' cannot have a type qualifier (C++) 300

E2090: Qualifier 'identifier' is not a class or namespace name (C++) 300

E2091: Functions cannot return arrays or functions (C++) 346

E2092: Storage class 'storage class' is not allowed here (C++) 300

E2093: Operator 'operator' not implemented in type 'type' for arguments of the same type (C++) 346

E2094: Operator 'operator' not implemented in type 'type' for arguments of type 'type' (C++) 346

E2095: String literal not allowed in this context (C++) 343

E2096: Illegal structure operation (C++) 300

E2097: Explicit instantiation only allowed at file or namespace scope (C++) 347

E2098: Explicit specialization declarator "template<>" now required (C++) 347

E2099: Explicit specialization only allowed at file or namespace scope (C++) 347

E2100: Invalid template declarator list (C++) 259

E2101: 'export' keyword must precede a template declaration (C++) 347

E2102: Cannot use template 'template' without specifying specialization parameters (C++) 260

E2103: Explicit instantiation must be used with a template class or function (C++) 347

E2104: Invalid use of template keyword (C++) 300

E2105: 'template' qualifier must specify a member template name (C++) 260

E2106: Explicit specialization must be used with a template class or function (C++) 347

E2107: Invalid use of template 'template' (C++) 260

E2108: Improper use of typedef 'identifier' (C++) 301

E2109: Not an allowed type (C++) 301

E2110: Incompatible type conversion (C++) 301

E2111: Type 'typename' may not be defined here (C++) 302

E2112: Unknown unit directive: 'directive' (C++) 347

E2113: Virtual function 'function1' conflicts with base class 'base' (C++) 301

E2114: Multiple base classes require explicit class names (C++) 301

E2115: Bit field too large (C++) 301

E2116: Bit fields must contain at least one bit (C++) 301

E2117: Bit fields must be signed or unsigned int (C++) 363

E2118: Bit fields must have integral type (C++) 348

E2119: User break (C++) 302

E2120: Cannot call 'main' from within the program (C++) 348

E2121: Function call missing) (C++) 302

E2122: Function call terminated by unhandled exception 'value' at address 'addr' (C++) 257

E2123: Class 'class' may not contain pure functions (C++) 302

E2124: Invalid function call (C++) 343

E2125: Compiler could not generate copy constructor for class

'class' OR Compiler could not generate default constructor for class 'class' OR Compiler could not generate operator = for class 'class' (C++) 348

E2126: Case bypasses initialization of a local variable (C++) 302

E2127: Case statement missing : (C++) 302

E2128: Case outside of switch (C++) 302

E2129: Character constant too long (or empty) (C++) 303

E2130: Circular property definition (C++) 348

E2131: Objects of type 'type' cannot be initialized with { } (C++) 348

E2132: Templates and overloaded operators cannot have C linkage (C++) 339

E2133: Unable to execute command 'command' (C++) 303

E2134: Compound statement missing closing brace (C++) 303

E2135: Constructor/Destructor cannot be declared 'const' or 'volatile' (C++) 303

E2136: Constructor cannot have a return type specification (C++) 303

E2137: Destructor for 'class' required in conditional expression (C++) 303

E2138: Conflicting type modifiers (C++) 303

E2139: Declaration missing ; (C++) 304

E2140: Declaration is not allowed here (C++) 304

E2141: Declaration syntax error (C++) 304

E2142: Base class 'class' contains dynamically dispatchable functions (C++) 304

E2143: Matching base class function 'function' has different dispatch number (C++) 305

E2144: Matching base class function 'function' is not dynamic (C++) 305

E2145: Functions 'function1' and 'function2' both use the same dispatch number (C++) 305

E2146: Need an identifier to declare (C++) 305

E2147: 'identifier' cannot start a parameter declaration (C++) 305

E2148: Default argument value redeclared for parameter 'parameter' (C++) 348

E2149: Default argument value redeclared (C++) 349

E2150: Type mismatch in default argument value (C++) 305

E2151: Type mismatch in default value for parameter 'parameter' (C++) 349

E2152: Default expression may not use local variables (C++) 306

E2153: Define directive needs an identifier (C++) 306

E2154: Cannot define 'identifier' using a namespace alias (C++) 304

E2155: Too many default cases (C++) 306

E2156: Default outside of switch (C++) 306

E2157: Deleting an object requires exactly one conversion to pointer operator (C++) 349

E2158: Operand of 'delete' must be non-const pointer (C++) 306

E2159: Trying to derive a far class from the huge base 'base' (C++) 306

E2160: Trying to derive a far class from the near base 'base' (C++) 306

E2161: Trying to derive a huge class from the far base 'base' (C++) 307

E2162: Trying to derive a huge class from the near base 'base' (C++) 307

E2163: Trying to derive a near class from the far base 'base' (C++) 307

E2164: Trying to derive a near class from the huge base 'base' (C++) 307

E2165: Destructor cannot have a return type specification (C++) 307

E2166: Destructor for 'class' is not accessible (C++) 307

E2167: 'function' was previously declared with the language 'language' (C++) 307

E2168: Division by zero (C++) 308

E2169: 'identifier' specifies multiple or duplicate access (C++) 308

E2170: Base class 'class' is included more than once (C++) 308

E2171: Body has already been defined for function 'function' (C++) 308

E2172: Duplicate case (C++) 308

E2173: Duplicate handler for 'type1', already had 'type2' (C++) 349

E2174: The name handler must be last (C++) 349

E2175: Too many storage classes in declaration (C++) 308

E2176: Too many types in declaration (C++) 309

E2177: Redeclaration of #pragma package with different arguments (C++) 350

E2178: VIRDEF name conflict for 'function' (C++) 350

E2179: virtual specified more than once (C++) 309

E2180: Dispid number already used by identifier (C++) 350

E2181: Cannot override a 'dynamic/virtual' with a 'dynamic/virtual' function (C++) 350

E2182: Illegal parameter to __emit__ (C++) 309

E2183: File must contain at least one external declaration (C++) 309

E2184: Enum syntax error (C++) 310

E2185: The value for 'identifier' is not within the range of 'type-name' (C++) 310

E2186: Unexpected end of file in comment started on line 'number' (C++) 310

E2187: Unexpected end of file in conditional started on line 'number' (C++) 310

E2188: Expression syntax (C++) 310

E2189: extern variable cannot be initialized (C++) 311

E2190: Unexpected closing brace (C++) 311

E2191: '__far16' may only be used with '__pascal' or '__cdecl' (C++) 261

E2192: Too few parameters in call (C++) 311

E2193: Too few parameters in call to 'function' (C++) 311

E2194: Could not find file 'filename' (C++) 311

E2195: Cannot evaluate function call (C++) 312

E2196: Cannot take address of member function 'function' (C++) 284

E2197: File name too long (C++) 311

E2198: Not a valid expression format type (C++) 312

E2199: Template friend function 'function' must be previously declared (C++) 262

E2200: Functions may not be part of a struct or union (C++) 312

E2201: Too much global data defined in file (C++) 313

E2202: Goto into an exception handler is not allowed (C++) 350

E2203: Goto bypasses initialization of a local variable (C++) 313

E2204: Group overflowed maximum size: 'name' (C++) 313

E2205: Illegal type type in __automated section (C++) 350

E2206: Illegal character 'character' (0x'value') (C++) 313

E2207: Implicit conversion of 'type1' to 'type2' not allowed (C++) 313

E2208: Cannot access an inactive scope (C++) 313

E2209: Unable to open include file 'filename' (C++) 314

E2210: Reference member 'member' is not initialized (C++) 314

E2211: Inline assembly not allowed in inline and template functions (C++) 314

E2212: Function defined inline after use as extern (C++) 314

E2213: Invalid 'expression' in scope override (C++) 343

E2214: Cannot have a 'non-inline function/static data' in a local class (C++) 315

E2215: Linkage specification not allowed (C++) 315

E2216: Unable to create turboc.$ln (C++) 315

E2217: Local data exceeds segment size limit (C++) 316

E2218: Templates can only be declared at namespace or class scope (C++) 315

E2219: Wrong number of arguments in call of macro 'macro' (C++) 316

E2220: Invalid macro argument separator (C++) 316

E2221: Macro argument syntax error (C++) 316

E2222: Macro expansion too long (C++) 316

E2223: Too many decimal points (C++) 316

E2224: Too many exponents (C++) 316

E2225: Too many initializers (C++) 316

E2226: Extra parameter in call (C++) 317

E2227: Extra parameter in call to function (C++) 317

E2228: Too many error or warning messages (C++) 317

E2229: Member 'member' has the same name as its class (C++) 317

E2230: In-line data member initialization requires an integral constant expression (C++) 264

E2231: Member 'member' cannot be used without an object (C++) 318

E2232: Constant/Reference member 'member' in class without constructors (C++) 317

E2233: Cannot initialize a class member here (C++) 317

E2234: Memory reference expected (C++) 317

E2235: Member function must be called or its address taken (C++) 318

E2236: Missing 'identifier' in scope override (C++) 343

E2238: Multiple declaration for 'identifier' (C++) 318

E2239: 'identifier' must be a member function (C++) 319

E2240: Conversion of near pointer not allowed (C++) 319

E2241: VCL style classes need virtual destructors (C++) 264

E2242: Specifier requires Delphi style class type (C++) 351

E2243: Array allocated using 'new' may not have an initializer (C++) 319

E2244: 'new' and 'delete' not supported (C++) 319

E2245: Cannot allocate a reference (C++) 319

E2246: x is not abstract public single inheritance class hierarchy with no data (C++) 264

E2247: 'member' is not accessible (C++) 351

E2248: Cannot find default constructor to initialize array element of type 'class' (C++) 351

E2249: = expected (C++) 264

E2250: No base class to initialize (C++) 320

E2251: Cannot find default constructor to initialize base class 'class' (C++) 352

E2252: 'catch' expected (C++) 352

E2253: Calling convention must be attributed to the function type, not the closure (C++) 352

E2254: : expected after private/protected/private (C++) 320

E2255: Use :: to take the address of a member function (C++) 320

E2256: No : following the ? (C++) 320

E2257: , expected (C++) 320

E2258: Declaration was expected (C++) 320

E2259: Default value missing (C++) 321

E2260: Default value missing following parameter 'parameter' (C++) 321

E2261: Use of dispid with a property requires a getter or setter (C++) 353

E2262: '__except' or '__finally' expected following '__try' (C++) 353

E2263: Exception handling not enabled (C++) 321

E2264: Expression expected (C++) 321

E2265: No file name ending (C++) 321

E2266: No file names given (C++) 321

E2267: First base must be VCL class (C++) 264

E2268: Call to undefined function 'function' (C++) 360

E2269: The function 'function' is not available (C++) 342

E2270: > expected (C++) 353

E2271: Goto statement missing label (C++) 321

E2272: Identifier expected (C++) 321

E2273: 'main' cannot be declared as static or inline (C++) 353

E2274: < expected (C++) 322

E2275: Opening brace expected (C++) 322

E2276: (expected (C++) 322

E2277: Lvalue required (C++) 322

E2278: Multiple base classes not supported for Delphi classes (C++) 322

E2279: Cannot find default constructor to initialize member 'identifier' (C++) 323

E2280: Member identifier expected (C++) 322

E2281: Identifier1 requires definition of Identifier2 as a pointer type (C++) 353

E2282: Namespace name expected (C++) 328

E2283: Use . or -> to call 'function' (C++) 323

E2284: Use . or -> to call 'member', or & to take its address (C++) 323

E2285: Could not find a match for 'argument(s)' (C++) 323

E2286: Overloaded function resolution not supported (C++) 324

E2287: Parameter 'number' missing name (C++) 324

E2288: Pointer to structure required on left side of -> or ->* (C++) 324

E2289: __published or __automated sections only supported for Delphi classes (C++) 353

E2290: 'code' missing] (C++) 324

E2291: brace expected (C++) 324

E2292: Function should return a value (C++) 324

E2293:) expected (C++) 325

E2294: Structure required on left side of . or .* (C++) 325

E2295: Too many candidate template specializations from 'specifier' (C++) 266

E2296: Templates not supported (C++) 325

E2297: 'this' can only be used within a member function (C++) 326

E2298: Cannot generate 'function' from template function 'template' (C++) 354

E2299: Cannot generate template specialization from 'specifier' (C++) 267

E2300: Could not generate a specialization matching type for 'specifier' (C++) 267

E2301: Cannot use templates in closure arguments -- use a typedef (C++) 354

E2302: No type information (C++) 327

E2303: Type name expected (C++) 327

E2304: 'Constant/Reference' variable 'variable' must be initialized (C++) 327

E2305: Cannot find 'class::class' ('class'&) to copy a vector OR Cannot find 'class'::operator=('class'&) to copy a vector (C++) 327

E2306: Virtual base classes not supported for Delphi classes (C++) 328

E2307: Type 'type' is not a defined class with virtual functions (C++) 354

E2308: do statement must have while (C++) 328

E2309: Inline assembly not allowed (C++) 320

E2310: Only member functions may be 'const' or 'volatile' (C++) 323

E2311: Non-virtual function 'function' declared pure (C++) 323

E2312: 'constructor' is not an unambiguous base class of 'class' (C++) 325

E2313: Constant expression required (C++) 325

E2314: Call of nonfunction (C++) 325

E2315: 'Member' is not a member of 'class', because the type is not yet defined (C++) 354

E2316: 'identifier' is not a member of 'struct' (C++) 326

E2317: 'identifier' is not a parameter (C++) 326

E2318: 'type' is not a polymorphic class type (C++) 354

E2319: 'identifier' is not a public base class of 'classtype' (C++) 326

E2320: Expression of scalar type expected (C++) 326

E2321: Declaration does not specify a tag or an identifier (C++) 325

E2322: Incorrect number format (C++) 328

E2323: Illegal number suffix (C++) 355

E2324: Numeric constant too large (C++) 328

E2325: Illegal octal digit (C++) 329

E2326: Use __declspec(spec1[, spec2]) to combine multiple __declspecs (C++) 355

E2327: Operators may not have default argument values (C++) 329

E2328: Classes with properties cannot be copied by value (C++) 355

E2329: Invalid combination of opcode and operands (C++) 329

E2330: Operator must be declared as function (C++) 329

E2331: Number of allowable option contexts exceeded (C++) 355

E2332: Variable 'variable' has been optimized and is not available (C++) 355

E2333: Class member 'member' declared outside its class (C++) 329

E2334: Namespace member 'identifier' declared outside its namespace (C++) 328

E2335: Overloaded 'function name' ambiguous in this context (C++) 329

E2336: Pointer to overloaded function 'function' doesn't match 'type' (C++) 330

E2337: Only one of a set of overloaded functions can be "C" (C++) 330

E2338: Overlays only supported in medium, large, and huge memory models (C++) 330

E2339: Cannot overload 'main' (C++) 330

E2340: Type mismatch in parameter 'number' (C++) 330

E2341: Type mismatch in parameter 'number' in call to 'function' (C++) 331

E2342: Type mismatch in parameter 'parameter' (C++) 331

E2343: Type mismatch in parameter 'parameter' in call to 'function' (C++) 331

E2344: Earlier declaration of 'identifier' (C++) 311

E2345: Access can only be changed to public or protected (C++) 331

E2346: 'x' access specifier of property 'property' must be a member function (C++) 356

E2347: Parameter mismatch in access specifier 'specifier' of property 'property' (C++) 356

E2348: Storage specifier not allowed for array properties (C++) 356

E2349: Nonportable pointer conversion (C++) 331

E2350: Cannot define a pointer or reference to a reference (C++) 332

E2351: Static data members not allowed in __published or __automated sections (C++) 357

E2352: Cannot create instance of abstract class 'class' (C++) 332

E2353: Class 'classname' is abstract because of 'member = 0' (C++) 357

E2354: Two operands must evaluate to the same type (C++) 332

E2355: Recursive template function: 'x' instantiated 'y' (C++) 333

E2356: Type mismatch in redeclaration of 'identifier' (C++) 333

E2357: Reference initialized with 'type1', needs lvalue of type 'type2' (C++) 333

E2358: Reference member 'member' needs a temporary for initialization (C++) 333

E2359: Reference member 'member' initialized with a non-reference parameter (C++) 357

E2360: Invalid register combination (e.g. [BP+BX]) (C++) 334

E2361: 'specifier' has already been included (C++) 334

E2362: Repeat count needs an lvalue (C++) 334

E2363: Attempting to return a reference to local variable 'identifier' (C++) 334

E2364: Attempting to return a reference to a local object (C++) 334

E2365: Member pointer required on right side of .* or ->* (C++) 335

E2366: Can't inherit non-RTTI class from RTTI base OR E2367 Can't inherit RTTI class from non-RTTI base (C++) 335

E2368: RTTI not available for expression evaluation (C++) 335

E2369: Cannot use the result of a property assignment as an rvalue' (C++) 358

E2370: Simple type name expected (C++) 358

E2371: sizeof may not be applied to a bit field (C++) 335

E2372: sizeof may not be applied to a function (C++) 335

E2373: Bit field cannot be static (C++) 335

E2374: Function 'function' cannot be static (C++) 335

E2375: Assembler stack overflow (C++) 360

E2376: statement missing (C++) 336

E2377: statement missing) (C++) 336

E2378: do-while or for statement missing ; (C++) 336

E2379: Statement missing ; (C++) 336

E2380: Unterminated string or character constant (C++) 336

E2381: Structure size too large (C++) 336

E2382: Side effects are not allowed (C++) 336

E2383: Switch selection expression must be of integral type (C++) 336

E2384: Cannot call near class member function with a pointer of type 'type' (C++) 337

E2386: Cannot involve parameter 'parameter' in a complex partial specialization expression (C++) 268

E2387: Partial specializations may not specialize dependent non-type parameters ('parameter') (C++) 269

E2388: Argument list of specialization cannot be identical to the parameter list of primary template (C++) 269

E2389: Mismatch in kind of substitution argument and template parameter 'parameter' (C++) 269

E2390: Type mismatch in parameter 'number' in template class name 'template' (C++) 337

E2391: Type mismatch in parameter 'parameter' in template class name 'template' (C++) 337

E2392: Template instance 'template' is already instantiated (C++) 270

E2393: Cannot take the address of non-type, non-reference template parameter 'parameter' (C++) 270

E2394: Too few arguments passed to template 'template' (C++) 337

E2395: Too many arguments passed to template 'template' (C++) 338

E2396: Template argument must be a constant expression (C++) 338

E2397: Template argument cannot have static or local linkage (C++) 270

E2398: Template function argument 'argument' not used in argument types (C++) 358

E2399: Cannot reference template argument 'arg' in template class 'class' this way (C++) 270

E2400: Nontype template argument must be of scalar type (C++) 338

E2401: Invalid template argument list (C++) 338

E2402: Illegal base class type: formal type 'type' resolves to 'type' (C++) 271

E2403: Dependent call specifier yields non-function 'name' (C++) 271

E2404: Dependent type qualifier 'qualifier' has no member type named 'name' (C++) 271

E2405: Dependent template reference 'identifier' yields non-template symbol (C++) 271

E2406: Dependent type qualifier 'qualifier' is not a class or struct type (C++) 272

E2407: Dependent type qualifier 'qualifier' has no member symbol named 'name' (C++) 272

E2408: Default values may be specified only in primary class template declarations (C++) 272

E2409: Cannot find a valid specialization for 'specifier' (C++) 272

E2410: Missing template parameters for friend template 'template' (C++) 273

E2411: Declaration of member function default parameters after a specialization has already been expanded (C++) 273

E2412: Attempting to bind a member reference to a dependent type (C++) 273

E2413: Invalid template declaration (C++) 315

E2414: Destructors cannot be declared as template functions (C++) 273

E2415: Template functions may only have 'type-arguments' (C++) 338

E2416: Invalid template function declaration (C++) 274

E2417: Cannot specify template parameters in explicit specialization of 'specifier' (C++) 274

E2418: Maximum instantiation depth exceeded; check for recursion (C++) 274

E2419: Error while instantiating template 'template' (C++) 358

E2420: Explicit instantiation can only be used at global scope (C++) 274

E2421: Cannot use local type 'identifier' as template argument (C++) 304

E2422: Argument kind mismatch in redeclaration of template parameter 'parameter' (C++) 275

E2423: Explicit specialization or instantiation of non-existing template 'template' (C++) 275

E2424: Template class nesting too deep: 'class' (C++) 358

E2425: 'member' is not a valid template type member (C++) 338

E2426: Explicit specialization of 'specifier' requires 'template<>' declaration (C++) 275

E2427: 'main' cannot be a template function (C++) 276

E2428: Templates must be classes or functions (C++) 338

E2429: Not a valid partial specialization of 'specifier' (C++) 276

E2430: Number of template parameters does not match in redeclaration of 'specifier' (C++) 276

E2431: Non-type template parameters cannot be of floating point, class, or void type (C++) 277

E2432: 'template' qualifier must name a template class or function instance' (C++) 339

E2433: Specialization after first use of template (C++) 337

E2434: Template declaration missing template parameters ('template<...>') (C++) 277

E2435: Too many template parameter sets were specified (C++) 277

E2436: Default type for template template argument 'arg' does not name a primary template class (C++) 277

E2437: 'typename' should be followed by a qualified, dependent type name (C++) 278

E2438: Template template arguments must name a class (C++) 278

E2439: 'typename' is only allowed in template declarations (C++) 278

E2440: Cannot generate specialization from 'specifier' because that type is not yet defined (C++) 278

E2441: Instantiating 'specifier' (C++) 278

E2442: Two consecutive dots (C++) 339

E2443: Base class 'class' is initialized more than once (C++) 339

E2444: Member 'member' is initialized more than once (C++) 339

E2445: Variable 'identifier' is initialized more than once (C++) 339

E2446: Function definition cannot be a typedef'ed declaration (C++) 339

E2447: 'identifier' must be a previously defined enumeration tag (C++) 340

E2448: Undefined label 'identifier' (C++) 340

E2449: Size of 'identifier' is unknown or zero (C++) 340

E2450: Undefined structure 'structure' (C++) 340

E2451: Undefined symbol 'identifier' (C++) 340

E2452: Size of the type is unknown or zero (C++) 341

E2453: Size of the type 'identifier' is unknown or zero (C++) 340

E2454: union cannot be a base type (C++) 341

E2455: union cannot have a base type (C++) 341

E2456: Union member 'member' is of type class with 'constructor' (or destructor, or operator =) (C++) 341

E2457: Delphi style classes must be caught by reference (C++) 359

E2458: Delphi classes have to be derived from Delphi classes (C++) 359

E2459: Delphi style classes must be constructed using operator new (C++) 359

E2460: Delphi style classes require exception handling to be enabled (C++) 360

E2461: '%s' requires run-time initialization/finalization (C++) 341

E2462: 'virtual' can only be used with non-template member functions (C++) 279

E2463: 'base' is an indirect virtual base class of 'class' (C++) 360

E2464: 'virtual' can only be used with member functions (C++) 341

E2465: unions cannot have virtual member functions (C++) 342

E2466: void & is not a valid type (C++) 342

E2467: 'Void function' cannot return a value (C++) 342

E2468: Value of type void is not allowed (C++) 342

E2469: Cannot use tiny or huge memory model with Windows (C++) 342

E2470: Need to include header <typeinfo> to use typeid (C++) 279

E2471: pragma checkoption failed: options are not as expected (C++) 261

E2472: Cannot declare a member function via instantiation (C++) 265

E2473: Invalid explicit specialization of 'specifier' (C++) 274

E2474: 'function' cannot be declared as static or inline (C++) 265

E2475: 'function' cannot be a template function (C++) 266

E2476: Cannot overload 'function' (C++) 356

E2477: Too few template parameters were declared for template 'template' (C++) 276

E2478: Too many template parameters were declared for template 'template' (C++) 277

E2479: Cannot have both a template class and function named 'name' (C++) 275

E2480: Cannot involve template parameters in complex partial specialization arguments (C++) 269

E2481: Unexpected string constant (C++) 268

E2482: String constant expected (C++) 268

E2483: Array dimension 'specifier' could not be determined (C++) 258

E2484: The name of template class 'class' cannot be overloaded (C++) 275

E2485: Cannot use address of array element as non-type

template argument (C++) 271

E2486: Cannot use address of class member as non-type template argument (C++) 273

E2487: Cannot specify default function arguments for explicit specializations (C++) 276

E2488: Maximum token reply depth exceeded; check for recursion (C++) 263

E2489: Maximum option context replay depth exceeded; check for recursion (C++) 263

E2490: Specialization within template classes not yet implemented (C++) 274

E2491: Maximum VIRDEF count exceeded; check for recursion (C++) 263

E2492: Properties may only be assigned using a simple statement, e.g. \"prop = value;\" (C++) 259

E2493: Invalid GUID string (C++) 263

E2494: Unrecognized __declspec modifier (C++) 262

E2495: Redefinition of uuid is not identical (C++) 268

E2496: Invalid call to uuidof(struct type|variable) (C++) 263

E2497: No GUID associated with type:'type' (C++) 267

E2498: Need previously defined struct GUID (C++) 266

E2499: Invalid __declspec(uuid(GuidString)) format (C++) 263

E2500: __declspec(selectany) is only for initialized and externally visible variables (C++) 268

E2501: Unable to open import file 'filename' (C++) 262

E2502: Error resolving #import: problem (C++) 262

E2503: Missing or incorrect version of TypeLibImport.dll (C++) 279

E2504: 'dynamic' can only be used with non-template member functions (C++) 261

E2505: Explicit instantiation requires an elaborated type specifier (i.e.,"class foo<int>") (C++) 259

E2506: Explicit specialization of 'specifier' is ambiguous: must specify template arguments (C++) 257

E2507: 'class' is not a direct base class of 'class' (C++) 268

E2508: 'using' cannot refer to a template specialization (C++) 279

E2509: Value out of range (C++) 258

E2510: Operand size mismatch (C++) 258

E2511: Unterminated macro argument (C++) 263

E2512: Cannot emit RTTI for return type of 'function' (C++) 267

E2513: Cannot emit RTTI for 'parameter' in 'function' (C++) 267

E2514: Cannot (yet) use member overload resolution during template instantiation (C++) 279

E2515: Cannot explicitly specialize a member of a generic template class (C++) 265

E2522: Non-const function 'function' called for const object (C++) 267

E2523: Non-volatile function 'name' called for volatile object (C++) 267

E2524: Anonymous structs/unions not allowed to have anonymous members in C++ (C++) 264

E2525: You must define _PCH_STATIC_CONST before including xstring to use this feature (C++) 257

E2526: Property 'name' uses another property as getter/setter; Not allowed (C++) 257

E2527: Option 'name' cannot be set via 'name' (C++) 258

E2528: Option 'name' must be set before compilation begins (C++) 258

E2529: Path 'path' exceeds maximum size of 'n' (C++) 268

E2530: Unrecognized option, or no help available (C++) 258

E2531: Parameter is an incomplete type (C++) 383

E2532: Constant in new expression requires an initializer (C++) 382

E2533: Parameter mismatch (wanted typename) (C++) 382

E2534: Integral constant expression expected (C++) 382

E2535: Incomplete type cannot be part of a throw specification (C++) 382

E2536: Incomplete type cannot be part of a exception declaration (C++) 381

E2537: Cannot create instance of abstract class (C++) 380

E2538: Static assert failed: '%s' (C++) 381

E2539: Constant expression expected (C++) 383

E2540: String literal expected (C++) 383

E2541: Attribute '%s' cannot be set (C++) 382

E2542: '%s' is marked 'final' and cannot be overriden (C++) 383

E2543: Combination of options 'options' is not permitted (C++) 381

E2544: Function exception specifications do not match (C++) 381

E2545: Enum underlying type must be an integral (C++) 382

E2546: Redeclaration of enum is not identical (C++) 382

E2547: ... expected (C++) 383

E2548: ... was unexpected; expression is not a variadic template pattern (C++) 381

E2549: Operand is not a parameter pack (C++) 381

E2550: No arguments can follow a variadic template in an argument list (C++) 381

E2551: Return statement not allowed in __finally block (C++) 384
E2552: This feature is not (yet) supported (C++) 383
E2553: %s mismatch in redeclaration of '%s' (C++) 383

W

W8000: Ambiguous operators need parentheses (C++) 362
W8001: Superfluous & with function (C++) 366
W8002: Restarting compile using assembly (C++) 362
W8003: Unknown assembler instruction (C++) 362
W8004: 'identifier' is assigned a value that is never used (C++) 375
W8005: Bit fields must be signed or unsigned int (C++) 302
W8006: Initializing 'identifier' with 'identifier' (C++) 366
W8007: Hexadecimal value contains more than three digits (C++) 366
W8008: Condition is always true OR W8008 Condition is always false (C++) 363
W8009: Constant is long (C++) 363
W8010: Continuation character \ found in // comment (C++) 364
W8011: Nonportable pointer comparison (C++) 374
W8012: Comparing signed and unsigned values (C++) 364
W8013: Possible use of 'identifier' before definition (C++) 375
W8014: Declaration ignored (C++) 365
W8015: Declare 'type' prior to use in prototype (C++) 371
W8016: Array size for 'delete' ignored (C++) 365
W8017: Redefinition of 'x' is not identical (C++) 368
W8018: Assigning 'type' to 'enumeration' (C++) 365
W8019: Code has no effect (C++) 370
W8020: 'identifier' is declared as both external and static (C++) 366
W8021: Handler for 'type1' hidden by previous handler for 'type2' (C++) 376
W8022: 'function1' hides virtual function 'function2' (C++) 367
W8023: Array variable 'identifier' is near (C++) 367
W8024: Base class 'class1' is also a base class of 'class2' (C++) 366
W8025: Ill-formed pragma (C++) 371
W8026: Functions with exception specifications are not expanded inline (C++) 377
W8027: Functions containing 'statement' are not expanded inline (C++) 378

W8028: Temporary used to initialize 'identifier' (C++) 373

W8029: Temporary used for parameter '???' (C++) 372

W8031: Temporary used for parameter 'parameter' OR W8029 Temporary used for parameter 'number' OR W8030 Temporary used for parameter 'parameter' in call to 'function' OR W8032 Temporary used for parameter 'number' in call to 'function' (C++) 372

W8032: Temporary used for parameter 2 in call to '???' (C++) 373

W8033: Conversion to 'type' will fail for members of virtual base 'class' (C++) 380

W8034: Maximum precision used for member pointer type 'type' (C++) 380

W8035: User-defined message (C++) 376

W8036: Non-ANSI keyword used: 'keyword' (C++) 378

W8037: Non-const function 'function' called for const object (C++) 369

W8038: constant member 'identifier' is not initialized (C++) 367

W8039: Constructor initializer list ignored (C++) 368

W8040: Function body ignored (C++) 369

W8041: Negating unsigned value (C++) 370

W8042: Initializer for object 'x' ignored (C++) 369

W8043: Macro definition ignored (C++) 368

W8044: #undef directive ignored (C++) 369

W8045: No declaration for function 'function' (C++) 374

W8046: Pragma option pop with no matching option push (C++) 377

W8047: Declaration of static function function ignored (C++) 370

W8048: Use qualified name to access member type 'identifier' (C++) 368

W8049: Use '> >' for nested templates Instead of '>>' (C++) 376

W8050: No type OBJ file present; disabling external types option. (C++) 377

W8051: Non-volatile function 'function' called for volatile object (C++) 369

W8052: Base initialization without a class name is now obsolete (C++) 362

W8053: 'ident' is obsolete (C++) 379

W8054: Style of function definition is now obsolete (C++) 371

W8055: Possible overflow in shift operation (C++) 379

W8056: Integer arithmetic overflow (C++) 376

W8057: Parameter 'parameter' is never used (C++) 370

W8058: Cannot create pre-compiled header: 'reason' (C++) 377

W8059: Structure packing size has changed (C++) 374

W8060: Possibly incorrect assignment (C++) 362

W8061: Initialization is only partially bracketed (C++) 367

W8062: Previous options and warnings not restored (C++) 379

W8063: Overloaded prefix operator 'operator' used as a postfix operator (C++) 371

W8064: Call to function with no prototype (C++) 363

W8065: Call to function 'function' with no prototype (C++) 363

W8066: Unreachable code (C++) 372

W8067: Both return and return with a value used (C++) 368

W8068: Constant out of range in comparison (C++) 365

W8069: Nonportable pointer conversion (C++) 372

W8070: Function should return a value (C++) 370

W8071: Conversion may lose significant digits (C++) 367

W8072: Suspicious pointer arithmetic (C++) 379

W8073: Undefined structure 'structure' (C++) 375

W8074: Structure passed by value (C++) 373

W8075: Suspicious pointer conversion (C++) 374

W8076: Template instance 'specifier' is already instantiated (C++) 283

W8077: Explicitly specializing an explicitly specialized class member makes no sense (C++) 283

W8078: Throw expression violates exception specification (C++) 376

W8079: Mixing pointers to different 'char' types (C++) 368

W8080: 'identifier' is declared but never used (C++) 364

W8081: Void functions may not return a value (C++) 375

W8082: Division by zero (C++) 365

W8083: Pragma pack pop with no matching pack push (C++) 282

W8084: Suggest parentheses to clarify precedence (C++) 282

W8085: Function 'function' redefined as non-inline (C++) 281

W8086: Incorrect use of #pragma alias "aliasName"="substituteName" (C++) 280

W8087: 'operator::operator==' must be publicly visible to be contained by a 'type' (C++) 283

W8089: 'type::operator<' must be publicly visible to be contained by a 'type' (C++) 283

W8090: 'type::operator<' must be publicly visible to be used with 'type' (C++) 283

W8091: 'type' argument 'specifier' passed to 'function' is a 'iterator category' iterator: 'iterator category' iterator required (C++) 283

W8092: 'type' argument 'specifier' passed to 'function' is not an iterator: 'type' iterator required (C++) 282

W8093: Incorrect use of #pragma codeseg [seg_name] ["seg_class"] [group] (C++) 280
W8094: Incorrect use of #pragma comment(<type> [,"string"]) (C++) 280
W8095: Incorrect use of #pragma message("string") (C++) 281
W8096: Incorrect use of #pragma code_seg(["seg_name"[,"seg_class"]]) (C++) 281
W8097: Not all options can be restored at this time (C++) 282
W8098: Multi-character character constant (C++) 281
W8099: Static main is not treated as an entry point (C++) 280
W8103: Path 'path' and filename 'filename' exceed maximum size of 'n' (C++) 379
W8104: Local Static with constructor dangerous for multi-threaded apps (C++) 384
W8105: %s member '%s' in class without constructors (C++) 281
W8105: Reference/Constant member 'identifier' in class without constructors (C++) 385
W8106: %s are deprecated (C++) 384
W8107: Type name expected (C++) 385
W8108: Constant in new expression requires an initializer (C++) 384
W8109: Parameter '%s' is a dependent type (C++) 385
W8110: Duplicate '%s' attribute directive ignored (C++) 384
W8112: Unresolved dependencies in expression (C++) 385
W8113: Inline function was declared with 'extern template' (C++) 384
