# 1 Scope of the Chapter

This chapter provides functions for the solution of large sparse systems of simultaneous linear equations. These include **iterative** methods for real nonsymmetric and symmetric, complex non-Hermitian and Hermitian linear systems and **direct** methods for general real linear systems. Further direct methods are currently available in Chapters F01 and F04.

## 2 Background to the Problems

This section is only a brief introduction to the solution of sparse linear systems. For a more detailed discussion see for example Duff *et al.* 1986 and Demmel *et al.* 1999 for direct methods, or Barrett *et al.* 1994 for iterative methods.

### 2.1 Sparse Matrices and Their Storage

A matrix A may be described as **sparse** if the number of zero elements is sufficiently large that it is worthwhile using algorithms which avoid computations involving zero elements.

If A is sparse, and the chosen algorithm requires the matrix coefficients to be stored, a significant saving in storage can often be made by storing only the nonzero elements. A number of different formats may be used to represent sparse matrices economically. These differ according to the amount of storage required, the amount of indirect addressing required for fundamental operations such as matrix-vector products, and their suitability for vector and/or parallel architectures. For a survey of some of these storage formats see Barrett *et al.* 1994.

Some of the functions in this chapter have been designed to be independent of the matrix storage format. This allows you to choose your own preferred format, or to avoid storing the matrix altogether. Other functions are the so-called **black-boxes**, which are easier to use, but are based on fixed storage formats. Three fixed storage formats for sparse matrices are currently used. These are known as co-ordinate storage (CS) format, symmetric co-ordinate storage (SCS) format and compressed column storage (CCS) format.

# 2.1.1 Co-ordinate storage (CS) format

This storage format represents a sparse matrix A, with **nnz** nonzero elements, in terms of three one-dimensional arrays – a double or **complex\*16** array **a** and two integer arrays **irow** and **icol**. These arrays are all of dimension at least **nnz**. **a** contains the nonzero elements themselves, while **irow** and **icol** store the corresponding row and column indices respectively.

For example, the matrix

$$A = \begin{pmatrix} 1 & 2 & -1 & -1 & -3 \\ 0 & -1 & 0 & 0 & -4 \\ 3 & 0 & 0 & 0 & 2 \\ 2 & 0 & 4 & 1 & 1 \\ -2 & 0 & 0 & 0 & 1 \end{pmatrix}$$

might be represented in the arrays a, irow and icol as

$$\begin{aligned} \mathbf{a} &= (1,2,-1,-1,-3,-1,-4,3,2,2,4,1,1,-2,1)\\ \mathbf{irow} &= (1,1,1,1,1,2,2,3,3,4,4,4,4,5,5)\\ \mathbf{icol} &= (1,2,3,4,5,2,5,1,5,1,3,4,5,1,5). \end{aligned}$$

Notes

- (i) The general format specifies no ordering of the array elements, but some functions may impose a specific ordering. For example, the nonzero elements may be required to be ordered by increasing row index and by increasing column index within each row, as in the example above. fllza is a utility function provided to order the elements appropriately (see Section 2.2).
- (ii) With this storage format it is possible to enter duplicate elements. These may be interpreted in various ways (e.g., raising an error, ignoring all but the first entry, all but the last, or summing).

f11.2 [NP3663/21]

### 2.1.2 Symmetric co-ordinate storage (SCS) format

This storage format is suitable for symmetric and Hermitian matrices, and is identical to the CS format described in Section 2.1.1, except that only the lower triangular nonzero elements are stored. Thus, for example, the matrix

$$A = \begin{pmatrix} 4 & 1 & 0 & 0 & -1 & 2 \\ 1 & 5 & 0 & 2 & 0 & 0 \\ 0 & 0 & 2 & 1 & 0 & -1 \\ 0 & 2 & 1 & 3 & 1 & 0 \\ -1 & 0 & 0 & 1 & 4 & 0 \\ 2 & 0 & -1 & 0 & 0 & 3 \end{pmatrix}$$

might be represented in the arrays a, irow and icol as

$$\mathbf{a} = (4, 1, 5, 2, 2, 1, 3, -1, 1, 4, 2, -1, 3).$$

**irow** = 
$$(1, 2, 2, 3, 4, 4, 4, 5, 5, 5, 6, 6, 6)$$
,

$$icol = (1, 1, 2, 3, 2, 3, 4, 1, 4, 5, 1, 3, 6).$$

### 2.1.3 Compressed column storage (CCS) format

This storage format also uses three one-dimensional arrays – a double or **complex\*16** array **a** and two integer arrays **irowix** and **icolzp**. The array **a** and **irowix** are of dimension at least nnz, while **icolzp** is of dimension at least n+1. **a** contains the nonzero elements, going down the first column, then the second and so on. For example, the matrix in Section 2.1.1 above will be represented by

$$\mathbf{a} = (1, 3, 2, -2, 2, -1, -1, 4, -1, 1, -3, -4, 2, 1, 1).$$

irowix records the row index for each entry in a, so the same matrix will have

**irowix** = 
$$(1, 3, 4, 5, 1, 2, 1, 4, 1, 4, 1, 2, 3, 4, 5)$$
.

**icolzp** records the index into **a** which starts each new column. The last entry of **icolzp** is equal to nnz+1. An empty column (one filled with zeros, that is) is signalled by an index that is the same as the next non-empty column, or nnz+1 if all subsequent columns are empty. The above example corresponds to

$$icolzp = (1, 5, 7, 9, 11, 16)$$

The example in Section 2.1.2 above will be represented by

$$\mathbf{a} = (4, 1, -1, 2, 1, 5, 2, 2, 1, -1, 2, 1, 3, 1, -1, 1, 4, 2, -1, 3)$$

**irowix** = 
$$(1, 2, 5, 6, 1, 2, 4, 3, 4, 6, 2, 3, 4, 5, 1, 4, 5, 1, 3, 6)$$

$$icolzp = (1, 5, 8, 11, 15, 18, 21)$$

# 2.2 Direct Methods

Direct methods for the solution of the linear algebraic system

$$Ax = b \tag{1}$$

aim to determine the solution vector x in a fixed number of arithmetic operations, which is determined a priori by the number of unknowns. For example, an LU factorization of A followed by forward and backward substitution is a direct method for (1).

If the matrix A is sparse it is possible to design **direct** methods which exploit the sparsity pattern and are therefore much more computationally efficient than the algorithms in Chapter F07, which in general take no account of sparsity. However, if the matrix is very large and sparse, then **iterative** methods, with an appropriate preconditioner, (see Section 2.3) may be more efficient still.

This chapter provides a direct LU factorization method for sparse real systems. This method is based on special coding for supernodes, broadly defined as groups of consecutive columns with the same nonzero structure, which enables use of dense BLAS kernels. The algorithms contained here come from the SuperLU software suite (see Demmel *et al.* 1999). An important requirement of sparse LU factorization is

keeping the factors as sparse as possible. It is well known that certain column orderings can produce much sparser factorizations than the normal left-to-right ordering. It is well worth the effort, then, to find such column orderings since they reduce both storage requirements of the factors, the time taken to compute them and the time taken to solve the linear system. The row reorderings, demanded by partial pivoting in order to keep the factorization stable, can further complicate the choice of the column ordering, but quite good and fast algorithms have been developed to make possible a fairly reliable computation of an appropriate column ordering for any sparsity pattern. We provide one such algorithm (known in the literature as COLAMD) through one function in the suite. Similar to the case for dense matrices, functions are provided to compute the LU factorization with partial row pivoting for numerical stability, solve (1) by performing the forward and backward substitutions for multiple right hand side vectors, refine the solution, minimize the backward error and estimate the forward error of the solutions, compute norms, estimate condition numbers and perform diagnostics of the factorization. For more details see Section 3.4.

It is also possible to use iterative method functions in this chapter to compute a direct factorization. Such methods are available for sparse real nonsymmetric, complex non-Hermitian, real symmetric positive-definite and complex Hermitian positive-definite systems. Further direct methods may be found in Chapters F01, F04 and F07.

#### 2.3 Iterative Methods

In contrast to the direct methods discussed in Section 2.2, **iterative** methods for (1) approach the solution through a sequence of approximations until some user-specified termination criterion is met or until some predefined maximum number of iterations has been reached. The number of iterations required for convergence is not generally known in advance, as it depends on the accuracy required, and on the matrix A – its sparsity pattern, conditioning and eigenvalue spectrum.

Faster convergence can often be achieved using a **preconditioner** (see Golub and Van Loan 1996 and Barrett *et al.* 1994). A preconditioner maps the original system of equations onto a different system

$$\bar{A}\bar{x} = \bar{b},\tag{2}$$

which hopefully exhibits better convergence characteristics. For example, the condition number of the matrix  $\bar{A}$  may be better than that of A, or it may have eigenvalues of greater multiplicity.

An unsuitable preconditioner or no preconditioning at all may result in a very slow rate or lack of convergence. However, preconditioning involves a trade-off between the reduction in the number of iterations required for convergence and the additional computational costs per iteration. Setting up a preconditioner may also involve non-negligible overheads. The application of preconditioners to real nonsymmetric, complex non-Hermitian, real symmetric and complex Hermitian systems of equations is further considered in Sections 2.4 and 2.5.

# 2.4 Iterative Methods for Real Nonsymmetric and Complex Non-Hermitian Linear Systems

Many of the most effective iterative methods for the solution of (1) lie in the class of non-stationary **Krylov subspace methods** (see Barrett *et al.* 1994). For real nonsymmetric and complex non-Hermitian matrices this class includes:

the restarted generalized minimum residual (RGMRES) method (see Saad and Schultz 1986);

the conjugate gradient squared (CGS) method (see Sonneveld 1989);

the polynomial stabilized bi-conjugate gradient (Bi-CGSTAB( $\ell$ )) method (see Van der Vorst 1989 and Sleijpen and Fokkema 1993);

the transpose-free quasi-minimal residual method (TFQMR) (see Freund and Nachtigal 1991 and Freund 1993).

Here we just give a brief overview of these algorithms as implemented in this chapter. For full details see the function documents for fl1bd and fl1br.

RGMRES is based on the Arnoldi method, which explicitly generates an orthogonal basis for the Krylov subspace span $\{A^k r_0\}$ ,  $k=0,1,2,\ldots$ , where  $r_0$  is the initial residual. The solution is then expanded onto the orthogonal basis so as to minimize the residual norm. For real nonsymmetric and complex non-

f11.4 [NP3663/21]

Hermitian matrices the generation of the basis requires a 'long' recurrence relation, resulting in prohibitive computational and storage costs. RGMRES limits these costs by restarting the Arnoldi process from the latest available residual every m iterations. The value of m is chosen in advance and is fixed throughout the computation. Unfortunately, an optimum value of m cannot easily be predicted.

CGS is a development of the bi-conjugate gradient method where the nonsymmetric Lanczos method is applied to reduce the coefficient matrix to tridiagonal form: two bi-orthogonal sequences of vectors are generated starting from the initial residual  $r_0$  and from the *shadow residual*  $\hat{r}_0$  corresponding to the arbitrary problem  $A^H\hat{x}=\hat{b}$ , where  $\hat{b}$  is chosen so that  $r_0=\hat{r}_0$ . In the course of the iteration, the residual and shadow residual  $r_i=P_i(A)r_0$  and  $\hat{r}_i=P_i(A^H)\hat{r}_0$  are generated, where  $P_i$  is a polynomial of order i, and bi-orthogonality is exploited by computing the vector product  $\rho_i=(\hat{r}_i,r_i)=\left(P_i(A^H)\hat{r}_0P_i(A)r_0\right)=\left(\hat{r}_0,P_i^2(A)r_0\right)$ . Applying the 'contraction' operator  $P_i(A)$  twice, the iteration coefficients can still be recovered without advancing the solution of the shadow problem, which is of no interest. The CGS method often provides fast convergence; however, there is no reason why the contraction operator should also reduce the once reduced vector  $P_i(A)r_0$ : this can lead to a highly irregular convergence.

Bi-CGSTAB( $\ell$ ) is similar to the CGS method. However, instead of generating the sequence  $\{P_i^2(A)r_0\}$ , it generates the sequence  $\{Q_i(A)P_i(A)r_0\}$  where the  $Q_i(A)$  are polynomials chosen to minimize the residual *after* the application of the contraction operator  $P_i(A)$ . Two main steps can be identified for each iteration: an OR (Orthogonal Residuals) step where a basis of order  $\ell$  is generated by a Bi-CG iteration and an MR (Minimum Residuals) step where the residual is minimized over the basis generated, by a method similar to GMRES. For  $\ell=1$ , the method corresponds to the Bi-CGSTAB method of Van der Vorst 1989. For  $\ell>1$ , more information about complex eigenvalues of the iteration matrix can be taken into account, and this may lead to improved convergence and robustness. However, as  $\ell$  increases, numerical instabilities may arise.

The transpose-free quasi-minimal residual method (TFQMR) (see Freund and Nachtigal 1991 and Freund 1993) is conceptually derived from the CGS method. The residual is minimized over the space of the residual vectors generated by the CGS iterations under the simplifying assumption that residuals are almost orthogonal. In practice, this is not the case but theoretical analysis has proved the validity of the method. This has the effect of remedying the rather irregular convergence behaviour with wild oscillations in the residual norm that can degrade the numerical performance and robustness of the CGS method. In general, the TFQMR method can be expected to converge at least as fast as the CGS method, in terms of number of iterations, although each iteration involves a higher operation count. When the CGS method exhibits irregular convergence, the TFQMR method can produce much smoother, almost monotonic convergence curves. However, the close relationship between the CGS and TFQMR method implies that the *overall* speed of convergence is similar for both methods. In some cases, the TFQMR method may converge faster than the CGS method.

Faster convergence can usually be achieved by using a **preconditioner**. A *left* preconditioner  $M^{-1}$  can be used by the RGMRES, CGS and TFQMR methods, such that  $\bar{A} = M^{-1}A \sim I_n$  in (2), where  $I_n$  is the identity matrix of order n; a *right* preconditioner  $M^{-1}$  can be used by the Bi-CGSTAB( $\ell$ ) method, such that  $\bar{A} = AM^{-1} \sim I_n$ . These are formal definitions, used only in the design of the algorithms; in practice, only the means to compute the matrix-vector products v = Au and  $v = A^Hu$  (the latter only being required when an estimate of  $||A||_1$  or  $||A||_\infty$  is computed internally), and to solve the preconditioning equations Mv = u are required, that is, explicit information about M, or its inverse is not required at any stage.

Preconditioning matrices M are typically based on incomplete factorizations (see Meijerink and Van der Vorst 1981), or on the approximate inverses occurring in stationary iterative methods (see Young 1971). A common example is the **incomplete** LU factorization

$$M = PLDUQ = A - R$$

where L is lower triangular with unit diagonal elements, D is diagonal, U is upper triangular with unit diagonals, P and Q are permutation matrices, and R is a remainder matrix. A **zero-fill** incomplete LU factorization is one for which the matrix

$$S = P(L + D + U)Q$$

has the same pattern of nonzero entries as A. This is obtained by discarding any fill elements (nonzero

elements of *S* arising during the factorization in locations where *A* has zero elements). Allowing some of these fill elements to be kept rather than discarded generally increases the accuracy of the factorization at the expense of some loss of sparsity. For further details see Barrett *et al.* 1994.

### 2.5 Iterative Methods for Real Symmetric and Complex Hermitian Linear Systems

Two of the best known iterative methods applicable to real symmetric and complex Hermitian linear systems are the conjugate gradient (CG) method (see Hestenes and Stiefel 1952 and Golub and Van Loan 1996) and a Lanczos type method based on SYMMLQ (see Paige and Saunders 1975). The description of these methods given below is for the real symmetric case. The generalization to complex Hermitian matrices is straightforward.

For the CG method the matrix A should ideally be positive-definite. The application of CG to indefinite matrices may lead to failure, or to lack of convergence. The SYMMLQ method is suitable for both positive-definite and indefinite symmetric matrices. It is more robust than CG, but less efficient when A is positive-definite.

Both methods start from the residual  $r_0 = b - Ax_0$ , where  $x_0$  is an initial estimate for the solution (often  $x_0 = 0$ ), and generate an orthogonal basis for the Krylov subspace span  $\{A^k r_0\}$ , for  $k = 0, 1, \ldots$ , by means of three-term recurrence relations (see Golub and Van Loan 1996). A sequence of symmetric tridiagonal matrices  $\{T_k\}$  is also generated. Here and in the following, the index k denotes the iteration count. The resulting symmetric tridiagonal systems of equations are usually more easily solved than the original problem. A sequence of solution iterates  $\{x_k\}$  is thus generated such that the sequence of the norms of the residuals  $\{\|r_k\|\}$  converges to a required tolerance. Note that, in general, the convergence is not monotonic.

In exact arithmetic, after n iterations, this process is equivalent to an orthogonal reduction of A to symmetric tridiagonal form,  $T_n = Q^T A Q$ ; the solution  $x_n$  would thus achieve exact convergence. In finite-precision arithmetic, cancellation and round-off errors accumulate causing loss of orthogonality. These methods must therefore be viewed as genuinely iterative methods, able to converge to a solution within a prescribed tolerance.

The orthogonal basis is not formed explicitly in either method. The basic difference between the two methods lies in the method of solution of the resulting symmetric tridiagonal systems of equations: the CG method is equivalent to carrying out an  $LDL^{\rm T}$  (Cholesky) factorization whereas the Lanczos method (SYMMLQ) uses an LQ factorization.

A preconditioner for these methods must be **symmetric and positive-definite**, i.e., representable by  $M = EE^{\mathrm{T}}$ , where M is nonsingular, and such that  $\bar{A} = E^{-1}AE^{-\mathrm{T}} \sim I_n$  in (2), where  $I_n$  is the identity matrix of order n. These are formal definitions, used only in the design of the algorithms; in practice, only the means to compute the matrix-vector products v = Au and to solve the preconditioning equations Mv = u are required.

Preconditioning matrices M are typically based on incomplete factorizations (see Meijerink and Van der Vorst 1977), or on the approximate inverses occurring in stationary iterative methods (see Young 1971). A common example is the **incomplete Cholesky factorization** 

$$M = PLDL^{\mathrm{T}}P^{\mathrm{T}} = A - R$$

where P is a permutation matrix, L is lower triangular with unit diagonal elements, D is diagonal and R is a remainder matrix. A **zero-fill** incomplete Cholesky factorization is one for which the matrix

$$S = P(L + D + L^{\mathrm{T}})P^{\mathrm{T}}$$

has the same pattern of nonzero entries as A. This is obtained by discarding any **fill** elements (nonzero elements of S arising during the factorization in locations where A has zero elements). Allowing some of these fill elements to be kept rather than discarded generally increases the accuracy of the factorization at the expense of some loss of sparsity. For further details see Barrett  $et\ al.$  1994.

f11.6 [NP3663/21]

### 3 Recommendations on Choice and Use of Available Functions

## 3.1 Types of Function Available

The direct method functions available in this chapter largely follow the LAPACK scheme in that four different functions separately handle the tasks of factorizing, solving, refining and condition number estimating. See Section 3.4.

The iterative method functions available in this chapter divide essentially into three types: basic functions, utility functions and Black Box functions.

Basic functions are grouped in suites of three, and implement the underlying iterative method. Each suite comprises a setup function, a solver, and a function to return additional information. The solver function is independent of the matrix storage format (indeed the matrix need not be stored at all) and the type of preconditioner. It uses **reverse communication**, i.e., it returns repeatedly to the calling program with the parameter **irevem** set to specified values which require the calling program to carry out a specific task (either to compute a matrix-vector product or to solve the preconditioning equation), to signal the completion of the computation or to allow the calling program to monitor the solution. Reverse communication has the following advantages.

- (i) Maximum flexibility in the representation and storage of sparse matrices. All matrix operations are performed outside the solver function, thereby avoiding the need for a complicated interface with enough flexibility to cope with all types of storage schemes and sparsity patterns. This also applies to preconditioners.
- (ii) Enhanced user interaction: the progress of the solution can be closely monitored by you and tidy or immediate termination can be requested. This is useful, for example, when alternative termination criteria are to be employed or in case of failure of the external functions used to perform matrix operations.

At present there are suites of basic functions for real symmetric and nonsymmetric systems, and for complex non-Hermitian systems.

Utility functions perform such tasks as initializing the preconditioning matrix M, solving linear systems involving M, or computing matrix-vector products, for particular preconditioners and matrix storage formats. Used in combination, basic functions and utility functions therefore provide iterative methods with a considerable degree of flexibility, allowing you to select from different termination criteria, monitor the approximate solution, and compute various diagnostic parameters. The tasks of computing the matrix-vector products and dealing with the preconditioner are removed from you, but at the expense of sacrificing some flexibility in the choice of preconditioner and matrix storage format.

**Black Box** functions call basic and utility functions in order to provide easy-to-use functions for particular preconditioners and sparse matrix storage formats. They are much less flexible than the basic functions, but do not use reverse communication, and may be suitable in many simple cases.

The structure of this chapter has been designed to cater for as many types of application as possible. If a Black Box function exists which is suitable for a given application you are recommended to use it. If you then decide you need some additional flexibility it is easy to achieve this by using basic and utility functions which reproduce the algorithm used in the Black Box, but allow more access to algorithmic control parameters and monitoring. If you wish to use a preconditioner or storage format for which no utility functions are provided, you must call basic functions, and provide your own utility functions.

# 3.2 Iterative Methods for Real Nonsymmetric and Complex Non-Hermitian Linear Systems

The suite of basic functions f11bd, f11be and f11bf implements either RGMRES, CGS, Bi-CGSTAB( $\ell$ ), or TFQMR, for the iterative solution of the real sparse nonsymmetric linear system Ax = b. These functions allow a choice of termination criteria and the norms used in them, allow monitoring of the approximate solution, and can return estimates of the norm of A and the largest singular value of the preconditioned matrix  $\bar{A}$ .

In general, it is not possible to recommend one of these methods in preference to another. RGMRES is popular, but requires the most storage, and can easily stagnate when the size m of the orthogonal basis is too small, or the preconditioner is not good enough. CGS can be the fastest method, but the computed

residuals can exhibit instability which may greatly affect the convergence and quality of the solution. Bi-CGSTAB( $\ell$ ) seems robust and reliable, but it can be slower than the other methods. TFQMR can be viewed as a more robust variant of the CGS method: it shares the CGS method speed but avoids the CGS fluctuations in the residual, which may give, rise to instability. Some further discussion of the relative merits of these methods can be found in Barrett *et al.* 1994.

The utility functions provided for real nonsymmetric matrices use the co-ordinate storage (CS) format described in Section 2.1.1. fl1da computes a preconditioning matrix based on incomplete LU factorization, and fl1db solves linear systems involving the preconditioner generated by fl1da. The amount of fill-in occurring in the incomplete factorization can be controlled by specifying either the level of fill, or the drop tolerance. Partial or complete pivoting may optionally be employed, and the factorization can be modified to preserve row-sums.

f11dd is similar to f11db, but solves linear systems involving the preconditioner corresponding to symmetric successive-over-relaxation (SSOR). The value of the relaxation parameter  $\omega$  must currently be supplied by you. Automatic procedures for choosing  $\omega$  will be included in the chapter at a future mark.

fl1dk applies the iterated Jacobi method to a system of linear equations and can be used as a preconditioner. However, the domain of validity of the Jacobi method is rather restricted; you should read the function document for fl1dk before using it.

fl1xa computes matrix-vector products for real nonsymmetric matrices stored in ordered CS format. An additional utility function fl1za orders the nonzero elements of a real sparse nonsymmetric matrix stored in general CS format.

The Black Box function f11dc makes calls to f11bd, f11be, f11bf, f11db and f11xa, to solve a real sparse nonsymmetric linear system, represented in CS format, using RGMRES, CGS, Bi-CGSTAB( $\ell$ ), or TFQMR, with incomplete LU preconditioning. f11de is similar, but has options for no preconditioning, Jacobi preconditioning or SSOR preconditioning.

For complex non-Hermitian sparse matrices there is an equivalent suite of functions. f11br, f11bs and f11bt are the basic functions which implement the same methods used for real nonsymmetric systems, namely RGMRES, CGS, Bi-CGSTAB( $\ell$ ) and TFQMR, for the solution of complex sparse non-Hermitian linear systems. f11dn and f11dp are the complex equivalents of f11da and f11db, respectively, providing facilities for implementing ILU preconditioning. f11dr implements a complex version of the SSOR preconditioner. f11dx implements a complex version of the iterated Jacobi preconditioner. Utility functions f11xn and f11zn are provided for computing matrix-vector products and sorting the elements of complex sparse non-Hermitian matrices, respectively. Finally, the Black Box functions f11dq and f11ds are complex equivalents of f11dc and f11de.

## 3.3 Iterative Methods for Real Symmetric and Complex Hermitian Linear Systems

The suite of basic functions f11gd, f11ge and f11gf implement either the conjugate gradient (CG) method, or a Lanczos method based on SYMMLQ, for the iterative solution of the real sparse symmetric linear system Ax = b. If A is known to be positive-definite the CG method should be chosen; the Lanczos method is more robust but less efficient for positive-definite matrices. These functions allow a choice of termination criteria and the norms used in them, allow monitoring of the approximate solution, and can return estimates of the norm of A and the largest singular value of the preconditioned matrix  $\bar{A}$ .

The utility functions provided for real symmetric matrices use the symmetric co-ordinate storage (SCS) format described in Section 2.1.2. f11ja computes a preconditioning matrix based on incomplete Cholesky factorization, and f11jb solves linear systems involving the preconditioner generated by f11ja. The amount of fill-in occurring in the incomplete factorization can be controlled by specifying either the level of fill, or the drop tolerance. Diagonal Markowitz pivoting may optionally be employed, and the factorization can be modified to preserve row-sums.

f11jd is similar to f11jb, but solves linear systems involving the preconditioner corresponding to symmetric successive-over-relaxation (SSOR). The value of the relaxation parameter  $\omega$  must currently be supplied by you. Automatic procedures for choosing  $\omega$  will be included in the chapter at a future mark.

fl1dk applies the iterated Jacobi method to a system of linear equations and can be used as a preconditioner. However, the domain of validity of the Jacobi method is rather restricted; you should read the function document for fl1dk before using it.

f11.8 [NP3663/21]

fl1xe computes matrix-vector products for real symmetric matrices stored in ordered SCS format. An additional utility function fl1zb orders the nonzero elements of a real sparse symmetric matrix stored in general SCS format.

The Black Box function f11jc makes calls to f11gd, f11ge, f11gf, f11jb and f11xe, to solve a real sparse symmetric linear system, represented in SCS format, using a conjugate gradient or Lanczos method, with incomplete Cholesky preconditioning. f11je is similar, but has options for no preconditioning, Jacobi preconditioning or SSOR preconditioning.

For complex Hermitian sparse matrices there is an equivalent suite of functions. fl1gr, fl1gs and fl1gt are the basic functions which implement the same methods used for real symmetric systems, namely CG and SYMMLQ, for the solution of complex sparse Hermitian linear systems. fl1jn and fl1jp are the complex equivalents of fl1ja and fl1jb, respectively, providing facilities for implementing incomplete Cholesky preconditioning. fl1jr implements a complex version of the SSOR preconditioner. fl1dx implements a complex version of the iterated Jacobi preconditioner. Utility functions fl1xs and fl1zp are provided for computing matrix-vector products and sorting the elements of complex sparse Hermitian matrices, respectively. Finally, the Black Box functions fl1jq and fl1js provide easy-to-use implementations of the CG and SYMMLQ methods for complex Hermitian linear systems.

#### 3.4 Direct Methods

The suite of functions fl1md, fl1me, fl1mf, fl1mg, fl1mh, fl1mk, fl1ml and fl1mm implement the COLAMD/SuperLU direct real sparse solver and associated utilities. You are expected to first call fl1md to compute a suitable column permutation for the subsequent factorization by fl1me. fl1mf then solves the system of equations. A solution can be further refined by fl1mh, which also minimizes the backward error and estimates a bound for the forward error in the solution. Diagnostics are provided by fl1mg which computes an estimate of the condition number of the matrix using the factorization output by fl1me, and fl1mm which computes the reciprocal pivot growth (a numerical stability measure) of the factorization. The two utility functions, fl1mk, which computes matrix-matrix products in the particular storage scheme demanded by the suite, and fl1ml which computes quantities relating to norms of a matrix in that particular storage scheme, complete the suite.

Another way of computing a direct solution is to choose specific parameters for the indirect solvers. For example, function fl1db solves a linear system involving the incomplete LU preconditioning matrix

$$M = PLDUQ = A - R$$

generated by f11da, where P and Q are permutation matrices, L is lower triangular with unit diagonal elements, U is upper triangular with unit diagonal elements, D is diagonal and R is a remainder matrix.

If A is nonsingular, a call to f11da with LFILL < 0 and DTOL = 0.0 results in a zero remainder matrix R and a **complete** factorization. A subsequent call to f11db will therefore result in a direct method for real sparse nonsymmetric systems.

If A is known to be symmetric positive-definite, f11ja and f11jb may similarly be used to give a direct solution. For further details see Section 8.4 of the document for f11ja.

Complex non-Hermitian systems can be solved directly in the same way using fl1dn and fl1dp, while for complex Hermitian systems fl1jn and fl1jp may be used.

Some other functions specifically designed for direct solution of sparse linear systems can currently be found in Chapters F01, F04 and F07. In particular, the following functions allow the direct solution of nonsymmetric systems:

Almost block-diagonal f01lh and f04lh

Sparse f01br (or f01bs) and f04ax

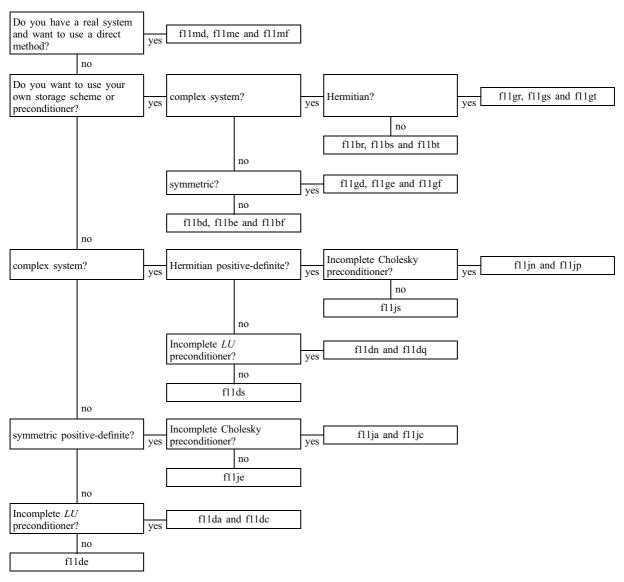

and the following functions allow the direct solution of symmetric positive-definite systems:

Variable band (skyline) f01mc and f04mc

Functions for the solution of band and tridiagonal systems can be found in Chapters F04 and F07.
